International Handbook of
**EARTHQUAKE
& ENGINEERING
SEISMOLOGY**

EDITED BY

William HK Lee
Hiroo Kanamori
Paul C Jennings
Carl Kisslinger

Part **A**

International Handbook of Earthquake and Engineering Seismology

This is Volume 81A in the
INTERNATIONAL GEOPHYSICS SERIES

A series of monographs and textbooks

Edited by RENATA DMOWSKA, JAMES R. HOLTON AND H. THOMAS ROSSBY

A complete list of books in this series appears at the end of this volume

International Handbook of Earthquake and Engineering Seismology

PART A

Edited by

William H. K. Lee, Hiroo Kanamori, Paul C. Jennings, and Carl Kisslinger

A project of the Committee on Education

International Association of Seismology and Physics of the Earth's Interior

in collaboration with

International Association for Earthquake Engineering

Published by Academic Press for

International Association of Seismology
and Physics of the Earth's Interior

ACADEMIC PRESS

Contents

Contributors	xi
Foreword	xvii
Preface	xix

I. History and Prefatory Essays

1. History of Seismology (D.C. Agnew)	3
2. Historical View of Earthquake Engineering (G.W. Housner)	13
3. The Jesuit Contribution to Seismology (A. Udías and W. Stauder)	19
4. International Seismology (R.D. Adams)	29
5. Synthesis of Earthquake Science Information and Its Public Transfer: A History of the Southern California Earthquake Center (K. Aki)	39
6. Continental Drift, Sea-Floor Spreading, and Plate/Plume Tectonics (S. Uyeda)	51
7. Earthquake Mechanisms and Plate Tectonics (S. Stein and E. Klosko)	69

II. Theoretical Seismology

8. Theoretical Seismology: An Introduction (A. Udías)	81
9. Seismic Ray Theory and Finite Frequency Extensions (C.H. Chapman)	103
10. Normal Modes of the Earth and Planets (P. Lognonné and E. Clévéde)	125
11. Inversion of Surface Waves: A Review (B. Romanowicz)	149
12. Earthquake Dynamics (R. Madariaga and K.B. Olsen)	175
13. Scattering and Attenuation of Seismic Waves in the Lithosphere (H. Sato, M. Fehler, and R.-S. Wu)	195
14. Earthquakes as a Complex System (D.L. Turcotte and B.D. Malamud)	209
15. Physics of Earthquakes (R. Teisseyre and E. Majewski)	229
16. Probabilistic Approach to Inverse Problems (K. Mosegaard and A. Tarantola)	237

III. Observational Seismology

17.	Challenges in Observational Seismology (W.H.K. Lee)	269
18.	Seismometry (E. Wielandt)	283
19.	Seismic Noise on Land and on the Seafloor (S.C. Webb)	305
20.	US Contribution to Digital Global Seismograph Networks (C.R. Hutt, H.F. Bolton, and L.G. Holcomb)	319
21.	The Structure and Interpretation of Seismograms (O. Kulháněk)	333
22.	Analysis of Digital Earthquake Signals (F. Scherbaum).	349
23.	Seismometer Arrays – Their Use in Earthquake and Test Ban Seismology (A. Douglas)	357
24.	Seismological Methods of Monitoring Compliance with the Comprehensive Nuclear Test-Ban Treaty (P.G. Richards)	369
25.	Volcano Seismology and Monitoring for Eruptions (S.R. McNutt)	383
26.	Three-Dimensional Crustal <i>P</i> -Wave Imaging of Mauna Loa and Kilauea Volcanoes, Hawaii (H.M. Benz, P. Okubo, and A. Villaseñor)	407
27.	Marine Seismology (K. Suyehiro and K. Mochizuki)	421
28.	Tsunamis (K. Satake)	437

IV. Earthquake Geology and Mechanics

29.	Geology of the Crustal Earthquake Source (R.H. Sibson)	455
30.	Paleoseismology (L.B. Grant)	475
31.	Using Earthquakes for Continental Tectonic Geology (J.A. Jackson)	491
32.	Rock Failure and Earthquakes (D.A. Lockner and N.M. Beeler)	505
33.	State of Stress Within the Earth (L.J. Ruff)	539
34.	State of Stress in the Earth's Lithosphere (M.D. Zoback and M.L. Zoback)	559
35.	Strength and Energetics of Active Fault Zones (J.N. Brune and W. Thatcher)	569
36.	Implications of Crustal Strain during Conventional, Slow, and Silent Earthquakes (M.J.S. Johnston and A.T. Linde)	589
37.	Estimating Earthquake Source Parameters from Geodetic Measurements (K.L. Feigl).	607
38.	Electromagnetic Fields Generated by Earthquakes (M.J.S. Johnston)	621

39. Earthquake-Related Hydrological and Geochemical Changes (C.-Y. King and G. Igarashi)	637
40. Case Histories of Induced and Triggered Seismicity (A. McGarr, D. Simpson, and L. Seeber).	647

V. Seismicity of the Earth

41. Global Seismicity: 1900–1999 (E.R. Engdahl and A. Villaseñor)	665
42. A List of Deadly Earthquakes in the World: 1500–2000 (T. Utsu)	691
43. Statistical Features of Seismicity (T. Utsu)	719
44. Relationships between Magnitude Scales (T. Utsu).	733
45. Historical Seismicity and Tectonics: The Case of the Eastern Mediterranean and the Middle East (N.N. Ambraseys, J.A. Jackson, and C.P. Melville).	747
46. Earthquakes and Archaeology (A. Nur).	765
47. Historical Seismology: The Long Memory of the Inhabited World (E. Guidoboni).	775
48. Earthquake History: Some Examples	791
48.1 Introduction (W.H.K. Lee).	791
48.2 California Earthquakes of $M \geq 5.5$: Their History and the Areas Damaged (T. Toppozada and D. Branum)	793
48.3 The Historical Earthquakes of India (S.P. Satyabala)	797
48.4 Historical Earthquakes in Japan (T. Usami)	799
48.5 Historical Earthquakes of the British Isles (R.M.W. Musson).	803
49. Macroseismology (R.M.W. Musson and I. Cčić).	807
50. USGS Earthquake Moment Tensor Catalog (S.A. Sipkin)	823

VI. Earth's Structure

51. The Earth's Interior (T. Lay)	829
52. Probing the Earth's Interior with Seismic Tomography (A. Curtis and R. Snieder).	861
53. Seismic Anisotropy (M. Cara)	875
54. Seismic Velocity Structure of the Continental Lithosphere from Controlled Source Data (W.D. Mooney, C. Prodehl, and N.I. Pavlenkova)	887
55. Seismic Structure of the Oceanic Crust and Passive Continental Margins (T.A. Minshull).	911
56. The Earth's Core (X. Song).	925
Index	Xi

Colour Plates appear between pages 12 and 13.

Foreword

Seismology is, in the truest sense of the word, a global science, not limited to political boundaries. Thus, it can only be effectively practiced through international cooperation.

Seismology is primarily an observational science. Quantitative measurements of seismic ground motion as a function of time require physically well defined, continuously recording instruments. Suitable seismographs of different design principles became available at the end of the 19th century. In the following years, a considerable number of seismograph stations were installed at sites around the globe. At the dawn of this century, some of these stations celebrate their 100th anniversary, as does the International Association of Seismology and Physics of the Earth's Interior (IASPEI).

When it became evident that seismic signals propagate through the Earth over large distances, the need for an international organization to coordinate, collect and distribute the data, and promote earthquake research arose. During two "International Conferences on Seismology", in 1901 and 1903 in Strasbourg, the establishment of an "International Association of Seismology" (IAS) was proposed. The association was inaugurated in 1904 and signed by 18 nations. This can be considered the root of what finally became the "International Association of Seismology and Physics of the Earth's Interior".

So it is appropriate to state that the present Handbook reflects and encompasses one hundred years of a very dynamical and successful history of scientific seismology. Of course it has been a long and rocky path with changes and interruptions, mainly caused by the international political scene during and after the two World Wars. In 1919, the International Union of Geodesy and Geophysics (IUGG) was created with the "Seismological Section" as one of the founding components. In 1933, the name was changed to "International Association of Seismology" of the IUGG. With the expansion of its scope to include material properties of the Earth's interior, it was renamed in 1951 to "International Association of Seismology and Physics of the Earth's Interior", as it is known today.

Along with the progress in instrumentation, the theoretical basis of wave propagation in the Earth was being developed for the evaluation and interpretation of the observed travel-time data. By the end of the 1930s, a rough and still valid first model of the structure of a spherically symmetric Earth existed. This is equivalent to a static picture of the Earth.

While in the first half of the 20th century scientific seismology developed mainly in Europe and Japan, after World War II, the center of research activity shifted to the USA.

A mighty impetus came with the installation of the first true worldwide network of homogeneous seismograph stations (WWSSN) by the US government. Originally justified for fundamental research in support of the search for means to detect and identify underground nuclear explosions, it turned out to be a powerful tool for a very fruitful period of basic scientific research on a wide range of problems in the science of the Earth.

In a third phase, modern seismology took full advantage of the great technical progress in digital technology from recent decades. Broadband digital seismographs with very high signal resolution provide a far superior data quality and make possible powerful application of digital data handling and analysis. Several hundred broadband digital seismographs now cover the globe and data from many of them are directly accessible in almost real time by fast telecommunication links.

A multitude of precise data has enabled us to resolve lateral heterogeneities in the Earth's structure by tomographic methods, and to study parameters of the seismic source. This empowered seismologists to deduce dynamic properties of the Earth such as fracture process, flow, temperature, and the stress field in the Earth. This has greatly improved our understanding of the driving mechanisms of plate tectonics and convection in mantle and core. In close interaction with experimental and theoretical high pressure/high temperature rock physics and chemistry, we have now also a realistic understanding of the material which constitutes the Earth's interior. Thus, the picture of the static Earth evolved to a picture of a dynamic Earth.

In addition to academic interest in the Earth's interior, earthquakes are also capable of paramount economical and sociological consequences. An important issue of seismology from the early times on has been the question of earthquake prediction. In the 1970s, some seismologists were quite optimistic that the problem could be solved fairly soon. A joint American–Soviet publication left only the choice between two alternative theoretical approaches. But with increasing database and experience, it became obvious that the problem is much more complex and fundamental, and general solutions are even now not in sight.

However, important branches of science and technology, such as Engineering Seismology and Earthquake Engineering, have developed in modern form during the past 50 years. These innovations provide powerful tools to estimate and to reduce building destruction, and consequently losses of lives. The seismic hazard or the potential ground shaking of an area by earthquakes can be estimated from the local

seismicity and seismotectonics, and from records of strong-motion accelerographs. The dynamic response of technical construction elements is investigated experimentally and by computer simulations. Together with social and economical aspects, it allows assessment of seismic risk for a certain region. Recommendations for earthquake resistant constructions form the content of “seismic building codes”.

This Handbook is a document of the great achievements that have been made during the past century by the very dynamically developing sciences of seismology and earthquake engineering. It presents the contributions of earthquake research to the scientific community and to our comprehension of the world. Great credit goes to the editors for attracting over 1200 of the most experienced and highly regarded experts from more than 50 countries to participate in this comprehensive and truly international work.

It is expected that this Handbook will become a standard work of seismology, which should be present in many libraries and research institutes. It is also a justification of the great amount of public funds that have been spent on earthquake research to date. It covers not only the history of our science but leads to the present day frontiers of our knowledge.

However, earthquakes and earthquake research will continue into the future as they have in the past. Earthquake recording and treatment of seismograms have to be carried out in a professional, scientific way. Therefore, the IASPEI Commission on Practice began some five years ago to write a “New Manual of Seismological Observatory Practice” (NMOSP) which will replace the 1979 edition. The old publication and the new manual in its latest available pre-publication version are attached as computer readable files on the Handbook CD-ROM. It is a very impressive work by itself and the NMSOP editor and contributors deserve our sincere thanks and high appreciation. The NMSOP will also certainly play an important role in the “International Training Courses on Seismology and Seismic Risk Assessment for Developing Countries” regularly held in different countries and co-sponsored by IASPEI.

Hans Berckhemer, Past President of IASPEI, 1975–1979.

Preface

Modern scientific investigations of earthquakes began in the 1880s, and the *International Association of Seismology* was organized in 1901–4 to promote collaboration of scientists and engineers in studying earthquakes. It became a Section (later Association) of the *International Union of Geodesy and Geophysics* in 1919, and the present *International Association of Seismology and Physics of the Earth's Interior* (IASPEI) in 1951. With the rapid advances in science during the 20th century, many branches of seismology developed and some excellent text books and monographs have been published on various seismological subjects and disciplines. However, there is no reference book that summarizes our present knowledge about earthquake and engineering seismology as a whole.

We think it is appropriate that such a reference work, international in scope, be published on the occasion of the Association's centennial. It is our hope that in addition to documenting the advances in most aspects of seismology, with the exception of exploration seismology, over the past century, this Handbook will help to foster more communication between seismologists and earthquake engineers.

Our aims for the Handbook are: (1) to summarize the well-established facts of earthquake and engineering seismology, (2) to review relevant theories, (3) to survey useful methods and techniques, (4) to summarize the historical development and current status of seismology in the member countries of IASPEI, and (5) to document and archive some basic seismic data. In collaboration with the International Association of Earthquake Engineering (IAEE), we also include national reports from member countries of IAEE. Since participation of IASPEI and IAEE member countries was voluntary, we have extensive but not complete coverage.

The Handbook consists of two printed volumes (Part A and Part B) and three CDs containing supplementary materials. Part A contains Chapters 1 through 56 plus one attached CD, and Part B contains Chapters 57 through 90 plus three appendices and two attached CDs. The Handbook is intended as a general reference on earthquake and engineering seismology, and also as a comprehensive “resource library” for anyone interested in earthquakes and related subjects.

We attempted to achieve these goals through three types of articles: (1) review articles of topics in theoretical seismology, observational seismology, earthquake geology and mechanics, seismicity of the Earth, structure of the Earth's interior, strong-motion seismology, earthquake engineering, earthquake prediction, and hazards mitigation, (2) national and institutional reports on seismology,

earthquake engineering, and physics of the Earth's interior, and (3) supplementary articles on history, general information, and seismological data.

The three CDs attached to the Handbook constitute a “digital” library of a few hundred volumes on seismology and earthquake engineering. Many authors of printed articles used the attached CDs to provide supplementary materials. For example, a few authors provided an expanded version of their printed-volume chapters, and several authors archived lengthy data sets, out-of-print books, or hard-to-find reports. In addition, there are chapters (summaries in print and details on CD) devoted to a global inventory of seismographic networks, a collection of seismological software, a global earthquake catalog of the 20th century, a collection of early seismic bulletins and some classic monographs and papers in seismology and earthquake engineering. We included many “historical” materials: histories and publication lists from many institutions in seismology and earthquake engineering, biographies of over 250 notable earthquake scientists and engineers now deceased, and biographical sketches from over 1,000 living active researchers. Finally, we included a technical glossary of terms that are frequently used in earthquake and engineering seismology in the printed Part B volume.

The one-page biographical sketches allow each individual to state concisely his or her major contributions or research interests, and a brief list of his or her most important publications. The more than 1,000 biographical sketches enhances and supplements the review chapters and national/institutional reports. We have also invited some prominent non-seismological researchers to contribute their biographical sketches in order to provide information that seismologists should be aware of.

The widespread use of the World Wide Web and the Internet beginning in the 1990s profoundly changes the way we communicate and disseminate information. In this Handbook, we have attempted to provide many useful web site addresses, and several data sets on the attached Handbook CDs can be explored using a Web browser. Although information on the CDs can not be changed, CDs provide an inexpensive way of archiving data and much faster access than via the Internet.

This Handbook is the result of a six-year project undertaken by the *IASPEI Committee on Education* in collaboration with the *International Association for Earthquake Engineering*. Planning, writing, and editing this Handbook involved four editors, 15 associate editors, 11 coordinators, over 250 authors,

and an advisory board of over 40 members. More than 1,200 scientists and engineers from over 50 countries participated in this project. Manuscripts for the printed Handbook were reviewed similarly to those submitted to a scientific journal. We are grateful to over 200 reviewers worldwide for improving the manuscripts. Thanks to the efforts of all these people we have largely achieved our goal of compiling a comprehensive reference work in earthquake and engineering seismology. However, given such a broad undertaking it is perhaps inevitable that articles on some topics (e.g., intraplate seismicity, deep earthquakes, general seismotectonics, recent advances in earthquake location, and earthquake resistant design) intended for inclusion in the Handbook were not, in the end, available for publication.

We thank Frank Cynar, the publishing editor at Academic Press, Jennifer Helé, his assistant, and Roopa Baliga, the production editor, for their patience in transforming several

thousand manuscript pages into the final printed volume. We also thank the following publishers: Academic Press, the American Geophysical Union, the Annual Reviews Inc., the Earthquake Engineering Research Institute, and the Seismological Society of America for permission to scan their copyrighted materials into computer readable files to form a significant part of a “digital library” on the attached CDs.

This Handbook project is a labor of love by volunteers, as no financial support was available from IASPEI or any funding agencies. We declined royalties and financial support from the publisher in order to retain the copyright by the IASPEI’s Committee on Education and to keep the price of this Handbook as low as possible.

History of Seismology

Duncan Carr Agnew

University of California at San Diego, La Jolla, California, USA

1. Introduction

At present seismology is the study of seismic sources (mostly earthquakes), the waves they produce, and the properties of the media through which these waves travel. In its modern form the subject is just over 100 years old, but attempts to understand earthquakes go back to the beginnings of science. The course of seismology, more than that of many other sciences, has been affected by its object of study: From Lisbon in 1755 through Kobe in 1995, destructive earthquakes have provoked scientific

interest, and, quite often, social support for seismic studies. Table 1 lists some earthquakes (and one explosion) that have had an impact on seismology.

This article describes the history of seismology up to about 1960, with a brief sketch of major themes since then. To cover this history in the space available requires a fair amount of selection. Any reading of the older literature shows that a great many ideas were suggested long before they became generally accepted: For example, the ideas that shaking is a wave propagated from a source, that some earthquakes (at least) are

TABLE 1 Some Events of Significance to the History of Seismology

Name	Date	Location	Magnitude	Importance
Lisbon	143 1755 Nov. 1	Gansu, China Azores-Cape St Vincent Ridge	7 8+	Possibly first instrumental record of unfelt shock Widespread seiche and tsunami: basis for theories of wave propagation
Calabria	1783 Feb. 5	Southern Italy	7+	First event studied by a scientific commission
Basilicata (Neapolitan)	1857 Dec. 16	Southern Italy	7	Detailed investigation by Mallet
Yokohama	1880 Feb. 22	Near south coast of Honshu, Japan	5.8	Led to Seismological Society of Japan
Casamicciola (Ischia)	1883 Jul. 28	Tyrrhenian Sea	6	Led to foundation of Italian seismological service
Vyernyi (Alma-Ata)	1887 Jun. 9	Lake Issyk-Kul, Krygyzstan	7.3	Stimulated Russian study of earthquakes
North Canterbury	1888 Aug. 31	South Island, New Zealand	7+	First scientific observation of strike-slip faulting
Nobi (Mino-Owari)	1889 Apr. 18	Near south coast of Honshu, Japan?	7+?	First teleseismic recording
	1891 Oct. 28	Western Honshu, Japan	8.4	Large surface rupture; led to Imperial Earthquake Investigation Committee
Assam	1897 Jun. 12	Northeastern India	8.7	Recognition of teleseismic primary and secondary phases
San Francisco	1906 Apr. 18	Central California	7.7	Large surface rupture; geodetic detection of off-fault motions; led to Seismological Society of America
Kulpa Valley	1909 Oct. 8	Northwestern Balkan region	6	Discovery of crustal phases
Kanto (Kwanto)	1923 Sep. 1	Near south coast of Honshu, Japan	7.9	Led to foundation of Earthquake Research Institute (Tokyo)
Buller (Murchison)	1929 Jun. 16	South Island, New Zealand	7.8	Stimulated local earthquake recording in New Zealand; inner-core phases in Europe
Ashkhabad	1946 Apr. 1	Unimak Island region	7.2	Led to tsunami warning system
	1948 Oct. 5	Turkmenistan-Iran border region	7.2	Stimulated Soviet earthquake program
RAINIER	1952 Nov. 4	Off east coast of Kamchatka	9.0	First suggested observation of free oscillations
	1957 Sep. 19	Southern Nevada	4.0	First underground nuclear explosion, helped stimulate VELA-UNIFORM program
Chilean	1960 May. 22	Off coast of Central Chile	9.5	First detection of free oscillations
Alaskan	1964 Mar. 28	Southern Alaska	9.2	Stimulated US earthquake-hazards program
Niigata	1964 Jun. 16	Near west coast of Honshu, Japan	7.5	Stimulus for modern Japanese earthquake programs
Xintiang	1966 Mar. 22	Northeastern China	7.0	Stimulated Chinese earthquake program

caused by faulting, and that the Earth contains a liquid core. I have therefore focused less on the earliest occurrence of an idea than the time when it became something seriously considered within the seismological community. To make the narrative more readable, the sources for particular statements are given in a separate set of notes, referenced through footnote numbers; these notes, the reference list, and a bibliography of the history of seismology, are all included on the attached Handbook CD.¹

2. Early Ideas about Earthquakes

The most common explanation given for earthquakes in early cultures was the same as for any other natural disaster: they were a manifestation of divine wrath. In European thought this idea did not disappear from scientific discussion until well into the 18th century. But two premodern cultures, the Chinese and the Greek, also developed naturalistic explanations for seismic shaking. Greek natural philosophers suggested a variety of causes for earthquakes; the most influential (and extensive) treatment extant was by Aristotle (ca. 330 BCE), who attributed earthquakes to winds (driven by an “exhalation,” the *pneuma*) blowing in underground caverns. The classical authors also attempted to classify earthquakes by different types of shaking: something that remained a mainstay of seismology for a long time, and still survives in popular terminology.²

Chinese ideas about earthquakes were put forth by various thinkers at roughly the same time as the Greek ones, the dominant idea also being that shaking was caused by the blocking of a subtle essence (the *qi*). After the Han dynasty (200 BCE), Imperial state orthodoxy associated natural disasters with dynastic decline; this led to systematic preservation of accounts of earthquakes in the official annals. China’s technology also produced the first seismoscope, invented in AD 132 by Zhang Heng. This well-known device, which reportedly signaled the direction of an earthquake as well as the occurrence of shaking, is supposed on at least one occasion to have responded to unfelt shaking; the mechanism of its operation remains obscure.³

The Aristotelian view of earthquakes (as of many other aspects of the world) remained the primary theory during the medieval periods of both Islam and Europe. With the decline of Aristotelian thought in early modern Europe, other ideas were put forward, though many of the writers were from northern Europe and so (unlike the Greeks) had little direct experience of earthquakes. They did, however, know about gunpowder: This new technology of chemical explosives suggested that earthquakes might be explosions in the Earth (or in the air); of the various chemical theories put forward, the most popular involved the combustion of pyrites or a reaction of iron with sulfur. Such theories also explained volcanic action; that the most seismic part of Europe, namely Italy, was also volcanic helped to support this association. In the

18th century the development of theories of electricity, and especially their application to lightning, provoked several theories that related earthquakes to electrical discharges. In England, much of this theorizing was stimulated by the occurrence of several damaging earthquakes in the year 1750.

However, the greatest stimulus to seismological thinking was undoubtedly the Lisbon earthquake of 1755, partly for its destructiveness, but even more for providing evidence of motion at large distances: It caused seiches over much of Europe. At least two writers, J. Michell (1761) and (much more obscurely) J. Drijhout (1765), proposed that this distant motion was caused by a wave propagating from a specific location, thus more clearly than before separating the earthquake source from the effects it produced. The type of wave envisaged was like a traveling wrinkle in a carpet; Michell also suggested that the vibrations close to the source were related to waves propagated through the elasticity of the rocks, as sound waves were known to propagate through the elasticity of the air. The elasticity and pressure of gases, more specifically of high-temperature steam, also provided Michell’s driving force for the earthquake itself, which he took to be caused by water vaporized by sudden contact with underground fires. (This steam also supported the propagation of waves to great distances.) Michell attempted to locate this “place of origin” by comparing the times of the seiche-inducing wave and the observed sea wave, and also hazarded a guess at the depth. While these ideas were not forgotten, they did not lead to any additional research, and certainly did not replace older theories of earthquakes.⁴

3. The Nineteenth Century to 1880

The expansion and professionalization of science in the 19th century meant that earthquake studies, like many other parts of science, could become a specialization, at least for a few scientists for part of their careers. One type of research that began in this period was the accumulation of large volumes of data, with the aim of finding underlying patterns—a style that has been called “Humboldtian” when applied to the Earth, but was in fact much more general. For earthquake studies, this meant the first systematic catalogs of shocks (as opposed to lists of catastrophes); leaders in this were K.A. Von Hoff and A. Perrey, the latter being a disciple of A. Quetelet, one of the founders of statistics. Many of these compilations were used to look for possible correlations between earthquake occurrence and astronomical cycles or meteorological events; this was one of the main topics of 19th-century seismology. Along with these catalogs came studies of individual shocks: Most European earthquakes after about 1820 stimulated some sort of special study, by individuals (often local professors) or by commissions set up by governments or local scientific societies. The first such commission was established after the Calabrian earthquake of 1783; a century later, one earthquake

(in Andalusia, 25 December 1884) would bring forth three commissions, one each from Spain, France, and Italy.

These special studies developed many of the tools and vocabulary still used to describe the felt effects of a large earthquake. One such tool, quite in keeping with the overall trend in science toward quantification, was scales of intensity of shaking: the first by P. Egen in 1828, followed by many others, notably those of M. de Rossi, F. Forel, these two working together, and G. Mercalli. The first cartographic application of an intensity scale, creating the isoseismal map, was by J. Nöggerath in 1847; in turn, the accumulation of maps stimulated questions about why the distribution of shaking was as observed, and to what extent it could be explained by waves radiating from a central source.

This period also saw the first efforts to relate earthquakes to other geological processes. Von Hoff was explicitly interested in this relationship and in the English-speaking world it was promoted most assiduously by C. Lyell, whose program of reducing all past geological change to current causes was aided by showing that earthquakes could cause vertical motions over large areas. Prominent examples of such motion in Lyell's treatment were the 1819 Rann of Cutch (India) and 1822 Chilean earthquakes, and later the 1835 Chilean and 1855 Wairarapa (New Zealand) earthquakes. The 1819 and 1855 earthquakes produced some of the earliest known examples of a break at the surface, though the first scientific observations of fault rupture did not take place until much later, by A. McKay in 1888 (North Canterbury) and by B. Koto in 1891 (Nobi).⁵

In retrospect, the basis for a different approach to earthquake study can be seen to have begun in 1829 to 1831, with investigations by S.D. Poisson into the behavior of elastic materials. He found that in such materials wave motions could occur, and were propagated at two speeds; the slower wave had particle motion perpendicular to the direction of propagation, and the faster one included dilatation of the material. A wave motion with transverse vibrations was of great interest because it offered a model for the recently discovered polarization of light, and many of the 19th-century investigations into elastic wave propagation were in fact made with optical observations in mind, attempting to explain light as transverse waves in an elastic "luminiferous ether." Notable examples were the study of G. Green (1838) into wave transmission across a boundary, and of G.G. Stokes (1850) on radiation from a limited source.⁶

These results were applied to earthquake studies by W. Hopkins (1847), and by R. Mallet (1848 onwards). Hopkins showed how timed observations of wave arrivals could be used to locate an earthquake, but went no further than this purely theoretical exercise. Mallet, a polymathic engineer, not only coined the term seismology but tried to develop it systematically as a science of earthquakes, observed through the waves they generate. Mallet constructed one of the most complete earthquake catalogs to date, which he summarized in

a map (Color Plate 1) that clearly delineates the seismic and aseismic regions of the world (1858). But Mallet aimed to do more than describe: Whenever possible he argued for the application of quantitative mechanical principles to determine how much, and in what direction, the ground moved in an earthquake. This quantitative emphasis is perhaps most notable in his 1862 study of the 1857 Basilicata (Neapolitan) earthquake, in which he attempted to estimate the direction of arrival of the shaking at many points, and so infer the location (and depth) of the source. It is also apparent in his earlier attempts (1851) to measure actual wave velocities from explosions and compare these with known elastic constants; he obtained much lower values than expected, which he attributed to inhomogeneity but which were more likely caused by insensitive instruments. Like Michell, Mallet believed that earthquakes were caused by the sudden expansion of steam as water met hot rock; because of the explosive nature of such a source, he believed that the earthquake waves would be almost entirely compressional.⁷

What was lacking in Mallet's otherwise comprehensive program was an adequate method of recording earthquake motion; though he and others proposed possible ways to do this, few of these schemes were actually built and even fewer were used by more than the inventor—though it was recognized early (for example, by Hopkins) that a network of instruments was really what was needed. The first instrument to automatically record the time and some aspects of the shaking was the seismoscope of L. Palmieri (1856), used in Italy and Japan. However, the first network of instruments, set up in Italy starting in 1873, was not intended to record earthquake shaking. Rather, these "tromometers," developed by T. Bertelli and M. de Rossi, were used to measure ongoing unfelt small motions, looking for changes in the amplitude or period of these related either to weather or to earthquakes, a study called "endogenous meteorology."⁸

4. The Birth of the "New Seismology": 1880–1920

With its emphasis on background vibrations, the substantial Italian effort turned out to be less fruitful than what happened in Japan as a consequence of the Meiji restoration of 1868: the establishment of modern science in a very seismic region. This was begun by the Japanese government bringing foreign experts (*yatoi*) to Japan, including professors well trained in the latest methods of physics and engineering. Of these, the most important for seismology was John Milne, who arrived in Japan in 1876 to be a professor (aged 26) at the Imperial College of Engineering in Tokyo. He made seismology his main interest after the earthquake of 22 February 1880, which also led to the foundation of the Seismological Society of Japan, with Milne as its effective leader. Such organization among the foreign experts

was soon paralleled by similar initiatives from the Japanese: the Meteorological Agency established (or rather, took over from Milne) a regular reporting system in 1883, and S. Sekiya became the world's first professor of seismology in 1886. The routine reporting of earthquakes allowed Sekiya's successor, F. Omori, to develop his law for the decay of aftershocks from data for the 1891 earthquake.

Even before the 1880 earthquake, attempts had been made by foreign scientists in Japan to record the time history of felt shaking. This developed into a rivalry between J.A. Ewing at the University of Tokyo, and Milne (with his colleague T. Gray). Ewing applied the horizontal pendulum to get the first good records of ground shaking (at what would now be regarded as the lower limit of strong motion) in 1880–1881. These records showed the motion to be much smaller than had been assumed, and also much more complicated: nothing like a few simple pulses and not the purely longitudinal motion envisaged by Mallet. Thus, as soon as seismologists had records of ground motion, they faced the problem that has been central to the science ever since: Explaining observed ground motion and deciding how much of the observed complication comes from the earthquake and how much from the complexities of wave propagation in the Earth.

While Milne may not have been the first to record earthquake shaking, he soon became a leading seismologist, not so much from any new ideas he brought to the subject as from his energy and flair for organization. Like Mallet, Milne aimed to study all aspects of earthquakes and elastic waves, but he added to Mallet's quantitative emphasis a regular use of instrumental measurements, often designing the instruments for the occasion. This regular use of quantitative instrumental records (not just by Milne) led contemporaries to term these activities "the new seismology."⁹

These instrumental improvements were largely focused on local shaking, but they formed the basis of quite different studies under the stimulus of an unexpected result. In Germany E. von Rebeur-Paschwitz had built sensitive horizontal pendulums for measuring tidal tilts, his interest being primarily astronomical. These showed transient disturbances, and he was able to correlate one of these, on 18 April 1889 (Fig. 1) with a Japanese earthquake reported in *Nature*. This demonstration that distant earthquakes could be recorded led to new developments in seismic instrumentation in Italy, by G. Agamemnone and A. Cancani, and in Japan, by Omori and Milne. Milne returned to England in 1895, bringing an enthusiasm for global seismology, a design for an inexpensive seismometer, and a long association with the British Association for the Advancement of Science (BAAS). Both he and von Rebeur-Paschwitz proposed in that year a global network of seismic instruments, but it fell to Milne, capitalizing in large part on the geographical reach of the British Empire and his BAAS connection, to install the first such network, with himself and an assistant as (in modern terms) data and analysis center combined.

FIGURE 1 The first recording of a distant earthquake. This photo reproduction is from von Rebeur-Paschwitz (1895) and is clearer than the engraving used in his 1889 article. This earthquake is often said to have been "in Tokyo," since the one report available was from there, but the description (see also Knott 1889) makes it clear that the shaking was just barely felt, so the shock must have been offshore. The magnitude in Table 1 is estimated from this record, applying the instrumental constants in Abe (1994).

Unfortunately, the global scope of Milne's network was not matched by the quality of his instruments: These low-gain undamped sensors, registering on a low-speed record, were adequate to detect large shocks but not to show the details of the waves from them. Major advances in instrumentation came from two physicists who had turned to seismology. The first was E. Wiechert, who (following a study of Italian instruments) introduced in 1904 his inverted-pendulum sensor, the first seismometer to be properly damped—something Wiechert's own theoretical developments, themselves new, showed to be important. The second was B.B. Golitsyn (Galitzin), who, beginning in 1906, applied electrodynamic sensors and photographically recording galvanometers to create instruments of unprecedentedly high sensitivity and accuracy.¹⁰

As these and other instruments were installed at observatories around the world, seismologists faced a new problem: sorting out the different "phases" observed, and relating them to different kinds of waves propagating inside the Earth. Theorizing about the Earth's interior was an active subject in the 19th century, but (rather like cosmology today) one in which a maximum of ingenuity was applied to minimal amounts of data. It was agreed that the depths of the Earth were hot and dense, but what parts were solid or liquid (or even gaseous) was the subject of much debate, though by the 1890s there was general agreement (from Kelvin and G.H. Darwin's tidal studies) that a large part of the Earth must be solid, and thus capable of transmitting the two known types of elastic waves, along with the elastic surface wave proposed by Rayleigh in 1885. But it was not known which of these wave types would actually occur, and how much they might become indistinguishably confused during propagation. Given that the Earth was an inhomogeneous body, and that rocks were anisotropic, seismologists had a wide range of options available to explain the observations.¹¹

The most obvious distinction was between the large "main phase" and the preceding "preliminary tremors," which

were early suggested to be surface waves and body waves, respectively. In 1900 R.D. Oldham, using measurements of the 1897 Assam earthquake, classified the preliminary tremors into two phases, which he identified with longitudinal and transverse body waves, the main phase being a surface wave. That this is the same identification that would be now made should not obscure its controversial nature at the time. For one thing, measurements of particle motion in the main phase showed motions quite different from Rayleigh's theory; for another, there was disagreement about the extent to which the records reflected tilting as opposed to horizontal motion. Perhaps because of these disagreements, in the proposal by Wiechert and van dem Borne in 1904 for designators, the letters *P*, *S*, and *L* referred only to the timing or form of the waves, not to their type.

This was by no means Wiechert's only contribution to global seismology; it would be fair to say that the work he and his students at Göttingen did between 1900 and 1920 made them the leaders of the subject. Already expert in optics and electrodynamics, Wiechert was able to apply his knowledge to waves in the Earth. With G. Herglotz, he developed the first solution to the geophysical inverse problem of deducing wave velocities from travel times (the forward version of this had been discussed by H. Benndorf). Another student, K. Zöppritz, determined a set of travel times that were used for some years, as well as working out the equations for transmission of elastic waves at an interface (earlier solved for wave energy by C.G. Knott). B. Gutenberg used the Herglotz–Wiechert method to determine a velocity profile—and in particular, to find the radius of the core (a region of decreased wave speed first proposed by Oldham in 1906) at a value very close to the modern one. And L. Geiger showed how to determine earthquake locations from distant observations using least-squares. Many of these names are still familiar, attesting to the extent to which Wiechert's group laid foundations for the field that have in many ways endured.

Of course, there were others contributing to wave-propagation studies. One was A. Mohorovičić, who used data from the 1909 Kulpa Valley earthquake in Croatia to study travel times at relatively short distances, and found additional phases which he explained by assuming a velocity discontinuity at about 50 km depth. A related development was the demonstration in 1911 by the mathematician A.E.H. Love that surface waves with particle motion transverse to the direction of propagation were possible in a layered Earth, thus satisfying the characteristics of the main phase in seismograms.¹²

5. The “Classical” Period: 1920–1960

In the forty years from 1880 to 1920, seismology had thus gone from being primarily a descriptive natural history of earthquakes to having a large (and mathematical) component concerned with the wave propagation within the Earth. The next

forty years (roughly) might well be called the “classical” period: A time during which many of the ideas first developed before 1920 were refined and improved, but without any substantial changes in aims or techniques. This period spans what is often taken to be a huge change in science (especially in the United States), from low-tech poverty before World War II to high-tech affluence after it; but while this change did occur for physics, it does not seem to have applied to much of seismology.

5.1 General Developments

Despite setbacks from both World Wars, the number of seismic stations increased substantially over these four decades; and the wider use of radio time signals after 1920 made timing more accurate (even if still poor by later standards). However, this growth was not at all standardized: individual organizations would set up one, or in a few cases, several new stations. The most “global” organization engaged in seismology at this time was probably the Jesuits, some of whose schools included seismological observatories. In the United States these observatories formed their own organization (the Jesuit Seismological Association), which provided one of the first rapid determinations of global epicenters. There were also international organizations: The International Seismological Association was founded to promote international cooperation in 1904, though it ceased to exist with the start of World War I. When revived in 1922, it created what was perhaps the most important entity for global seismic research, namely the International Seismological Summary (ISS), in many ways the continuation of Milne's efforts in earthquake location, which had been continued after his death by H.H. Turner and the BAAS. Through the occasional exchange of records, the regular exchange of station bulletins, and the ISS, information collected worldwide was available to individual researchers. Seismologists thus had what would now perhaps be called a “virtual” global network, something which greatly stimulated studies of seismic waves at great distances.¹³

While such wave-propagation studies were a great research opportunity for many scientists, they were also a departure from seismology's previous focus on earthquakes and their effects—and were viewed by some as an abandonment of the most useful part of the subject. One response was to develop instruments appropriate for studying nearby earthquakes, a strategy pursued by H.O. Wood in southern California in the 1920s. This resulted in a new and more sensitive instrument developed by himself and J.A. Anderson, as well as more sensitive electromagnetic seismometers, and the strain seismometer (both invented by H. Benioff). The Wood–Anderson, in particular, made southern California a model local seismic network, in a style soon copied from northern California to New Zealand. The quality of data available in California helped to attract the most productive of Wiechert's pupils, B. Gutenberg, to a position in Pasadena in 1930, a move which

(as in other parts of science) transplanted the outstanding quality of German science to an American setting.¹⁴

Another shift from Germany to America happened in this period, namely the application of seismology to subsurface exploration, usually for oil. The pioneer here was yet another student of Wiechert's, L. Mintrop, who had for his thesis developed a portable seismograph to measure waves generated by a falling weight. After wartime experiences in artillery location (also influential for many Americans), he formed an exploration company, which began work along the Gulf Coast (Mexico and United States) at about the same time as several US groups. From this beginning, exploration seismology grew rapidly and became a field dominated by US companies.¹⁵ Another "applied" area in which much early work was done in the United States was the recording of strong ground motion, begun in the 1930s (and treated in detail in an accompanying article).

5.2 First-Arrival Seismology: Global and Local Earth Structure

The main problem of instrumental seismology in this period remained that of relating observed bursts of energy on the seismic record ("arrivals") to elastic waves in the Earth. This was, for global seismology, a period of rapid progress: By 1940 the seismic-wave velocity structure of the mantle and core had been worked out in terms that remain little altered. Many travel-time investigations were "special studies" of global recordings from particular earthquakes: usually those that could be well located from other data. H. Jeffreys and K.E. Bullen took a quite different approach, using global data from the International Seismological Summary to iteratively construct improved epicenters and travel times, with due attention to statistical problems throughout. This analysis (and improved timekeeping) showed that many of the complications invoked by earlier seismologists were superfluous: The Earth is in fact a nearly spherically symmetric body, with only a few major internal discontinuities. One of these, the core-mantle boundary, was shown by Jeffreys in 1926 to separate a solid from a fluid region, based on the difference between mantle rigidities found seismically and whole-earth rigidities from earth tides. That the core itself contained a discontinuity was shown by I. Lehmann in 1936, using records of New Zealand earthquakes antipodal to the densely spaced stations of Europe. This finding of the inner core may be said to have completed the discovery phase of exploration of the inside of the Earth, though not its detailed mapping.

On more local scales there were a number of studies of crustal velocity structure using earthquakes and the occasional large explosion (usually detonated for some other purpose, or an accident). The results were interpreted in the framework given by Mohorovičić, finding the depth of crust-mantle discontinuity and sometimes of other velocity discontinuities (notably one first suggested by V. Conrad) as well. This is one

branch of seismology that did change significantly after World War II: There were then several programs that used large-scale seismic refraction to determine crustal structure. In the United States the pioneering postwar land-based program was by M. Tuve and H. Tatel. A program of land-based "deep-seismic sounding" was begun in the USSR before World War II by V.A. Gamburtsev, and greatly expanded after it. A similar pattern, of modest prewar beginnings and huge postwar expansion, also applied to seismic measurements at sea, led by M.N. Hill in Great Britain, and M. Ewing and R.W. Raitt in the United States.¹⁶

5.3 Seismic Geography

While the compilation of earthquake catalogs in the 19th century reached its culmination in the massive (and mostly unpublished) lists of F. Montessus de Ballore, the global picture of seismicity stood to be greatly improved by instrumental recording—though for many decades errors in the data and travel times combined to give a picture that, while more complete, was rather blurred. The first major advance from instrumental measurements came from the dense local network in Japan, which enabled K. Wadati to distinguish (in 1927) between deep and shallow earthquakes. Wadati's results, combined with global travel-time data (which had suggested great depths for some earthquakes) cleared up the longstanding problem of earthquake depth, and showed that deep earthquakes were relatively restricted in their distribution. The other advance in seismic geography grew out of the sensitivity of the local network in southern California, which detected many small earthquakes that had to be clearly distinguished from larger, damaging ones. This led C.F. Richter, transforming another idea of Wadati's, to develop a "magnitude" scale for the size of the earthquakes: As any seismologist who has had to explain it to the public knows, it is not such an obvious concept as it might seem. Gutenberg and Richter soon extended it from southern California shocks to earthquakes throughout the world. The magnitude scale, combined with the distinction between earthquakes of various depths, and the more reliable locations possible with improved travel times, came together in Gutenberg and Richter's study of the seismicity of the Earth (1941, and later revisions). This delineated, better than before, the belts of major seismicity and large aseismic regions, giving a synoptic view of current global activity that influenced tectonic theories. The magnitude scale also made possible estimates of the distribution of earthquakes by size: This magnitude-frequency relation and its parametric description (the *b*-value) remain a basic relationship of seismology.¹⁷

5.4 Earthquake Mechanism

If earthquake distribution was greatly clarified between 1920 and 1960, the same could not be said of seismologists' understanding of what actually happened at the source of seismic

waves. By the 1920s there was little doubt that earthquakes and faults were closely related, though a respectable minority of seismologists maintained that the faulting associated with earthquakes was not the cause but an effect. In this matter seismologists tended to be influenced by the earthquakes and faults they knew best, so for Americans the paradigmatic event was the 1906 California earthquake. This exhibited large motions not just on the fault but also at a distance, leading H.F. Reid to state (1910) the theory of elastic rebound, according to which the earthquake is caused by the release of stress built up along a fault.

The problem for seismologists was, as it still is, to relate what happened at the earthquake source to the seismograms observed. Given that Golicyn (Galitzin) had shown that the first motion of the *P* wave pointed directly toward (or away from) the epicenter, seismologists looked for patterns in the first motion as recorded at an observatory, or seen at several observatories around an earthquake. The latter approach required a large number of stations, which were available only (for local records) in Japan; Japanese seismologists for some time were the leaders in studying this topic. The first observational results were from T. Shida, who in 1917 showed a pattern of first motion divided into quadrants separated by nodal lines—though he found other patterns as well (Fig. 2). The first theoretical treatment was by H. Nakano in 1923, in a paper which examined the first motion from isolated forces and couples. Of little influence in Japan (nearly all copies were destroyed in the fire after the 1923 Kanto earthquake), a copy of this paper reached P. Byerly in California. By 1938 Byerly had developed a method (extended distances) for plotting the

distribution of first motions recorded globally in such a way as to identify nodal planes at the source. Apparently because of its intuitive match with the elastic rebound concept, he chose from Nakano's source models the single couple as representative of faulting.

Starting from Shida's initial investigation, there was a rapid development of first-motion studies in Japan, both theoretical and observational. It was soon observed, by S.T. Nakamura and S.I. Kunitomi, that the nodal lines coincided with geotectonic trends, strengthening the idea that seismic waves were produced by faulting. H. Honda showed that one implication of the simplest interpretation was false, namely, that the amplitudes of first motions would be largest close to the plane corresponding to the fault. Honda also argued that a double-couple system of forces was required to represent stress relaxation at the times of earthquakes; such a mechanism would produce two indistinguishable nodal planes. This view was itself soon challenged by M. Ishimoto, who argued that the distributions of first motions for many earthquakes were in better accord with conical nodal surfaces rather than planes, implying a distribution of forces that would now be called a compensated linear vector dipole. Ishimoto explained this as being consistent with magma intrusion causing both the earthquake and the faulting.

Ishimoto's interpretation of nodal lines created a controversy restricted to Japanese seismologists, perhaps because the associated magma theory was unappealing elsewhere. But other questions of earthquake mechanism were debated more widely—though with a tendency for the positions taken to coincide with nationality. After World War II earthquake-mechanism studies in Japan, led by Honda, favored a double-couple of forces as the source representation. An independent Soviet program on this subject began after 1948 under the leadership of V.I. Keilis-Borok, and developed methods for mechanism determination that made use, in principle, of first motions and amplitudes of both *P* and *S* waves; their results were interpreted as showing, most often, a single-couple source (for which the *S*-wave distribution, unlike that of the *P*-wave, differs from that for a double couple). Both Soviet and Japanese seismologists worked with local earthquakes. The systematic application of Byerly's techniques to large global earthquakes was undertaken by J. Hodgson and co-workers in Canada, with the results largely being interpreted both in terms of fault planes (taken to imply a single couple) or stresses (a double couple). Attempts to use *S* waves to discriminate between these models were not especially successful, nor were efforts to compile maps of inferred stress directions and relate these to regional tectonics.¹⁸

FIGURE 2 An early plot of first motions, from Shida (1929), showing one example used in his unpublished 1917 work. Note that the source pictured, while equivalent to a double-couple, is not shown as one.

5.5 Surface Waves

Though the period from 1920 through 1960 can be viewed as the heyday of “travel-time seismology,” it was not without attempts to interpret other parts of the seismogram. Once it was

clear that what had been called the “principal part” was a combination of Love and Raleigh waves, it became possible to use measurements of their velocities to determine shallow structure—a possibility made difficult by the computational burden of finding wave velocities for even very simple structures. Early results by G.H. Angenheister (yet another of Wiechert’s students) showed Rayleigh-wave velocities that were higher along oceanic than along continental paths. Subsequent studies through 1940 confirmed that oceanic paths showed faster velocities, implying a thinner crust—though the estimates of ocean crustal thickness varied, from 40 km to less than 10 km. Much about the observations, notably the long coda often associated with Rayleigh waves, remained unexplained.

The 1950s saw further developments in surface-wave studies, most notably in the program led by M. Ewing and F. Press. Ewing had had considerable experience with dispersive wave propagation through his ocean-acoustics work during World War II, and also had seismic refraction evidence against a thick crust under the ocean. He and Press were able to show that the structure seen from refraction indeed fit observations quite well, even explaining the coda. They and their coworkers went on to study surface waves over a variety of paths, to develop a new design of seismometer for better recording of the longest periods, to install several such instruments in a global network intended for surface-wave studies, and to publish a treatise covering the entire subject of elastic waves propagating along boundaries. This treatise included, though it did not emphasize, the improved computational method that N.A. Haskell had developed for computing dispersion in multilayered media—a method that was to become the basis for many later developments in seismic-wave computation.¹⁹

6. From 1960 on: The Modern Era

In many ways the 1960s brought major changes, and much growth, to seismology. Rather than trying to cover every subject, I sketch new trends that can be seen, retrospectively, to be important; I have not tried to associate ideas with individuals. The most important new development is that seismology became what physics had been since the 1940s, a science viewed as relevant to national security—in this case not for the weapons it could build, but for those it could detect. The first nuclear explosion, in 1945, was detected seismically, and US investigations of detection included seismology from their beginnings in 1947; but in an era of atmospheric testing seismic methods took third place to infrasound and radionuclide collection (though even third place was enough to produce significant funding in the United States). With the pressure to move testing underground, seismic methods became more important—and the results from the RAINIER test, and the US–Soviet debates over how to interpret them and data from other underground tests, showed the inadequacy of existing

knowledge. A US government panel (led by L.V. Berkner) recommended a large-scale program of “fundamental research in seismology.” This resulted in the creation in 1960 of the VELA-UNIFORM program—which, though a project funded by the US government, provided support to a large number of seismologists outside the United States. The interest in this project, and in seismic means of detection, only increased with the Limited Test Ban Treaty of 1963, which moved most tests underground. A large fraction of the VELA-UNIFORM funds went for improved instrumentation, including a considerable amount for seismic array development (also pursued by test-detection groups in the UK and the USSR). VELA-UNIFORM’s most important instrumental contribution to seismology was certainly the World Wide Standard Seismograph Network (WWSSN). This provided seismologists, for the first time, with easy access to records from standardized and well-calibrated sensors spread around the world. These data improved old results (e.g., on earthquake distribution) and made possible new ones; every subsequent global network has been modeled on the WWSSN style of operation.²⁰

Much of what seismologists did with WWSSN data would not have been possible without the other tool that became common at the time: rapid computation. As computing costs fell, and available funds rose, seismologists were able to speed up calculations that previously had taken up much time (epi-center location) and begin to do things that the labor of computation had ruled out before, such as compute surface wave dispersion in realistic structures. But the effect of the computer was not just to allow seismologists to model complex structures; it also gave them new ways to look at data. The ideas of signal processing and Fourier analysis, developed largely by statisticians and electrical engineers, began to make their way into seismology, to show what could be done with waveforms beyond timing them.

The year 1960 brought an impressive demonstration of this new style of seismology, with the first detection of the Earth’s free oscillations. The oscillations of an elastic sphere had been investigated by S.D. Poisson in 1829 (before he studied elastic waves), and some approximate periods of oscillation for a somewhat realistic (but homogeneous) Earth were worked out by H. Lamb (1883) and A.E.H. Love (1911). Following a large earthquake in 1952 H. Benioff believed that he had observed the gravest mode of oscillation, with a period of 52 minutes. But to see how this result compared with that expected it was necessary to compute the periods for a realistic Earth. This was done in 1959 by Z. Alterman, H. Jarosch, and C.L. Pekeris, using an early electronic computer. The occurrence of the 1960 Chilean earthquake spurred several groups to apply the novel techniques of Fourier analysis to their records. The demonstration, at the 1960 IUGG meeting, that the peaks in these transformed records matched the computed periods of oscillation, is a marker of the advent of new seismological techniques. Free-oscillation investigations flourished from then on, contributing to more precise Earth models, to the

advent of digital recording of seismic data, and (by being the first substantial demonstration of geophysical inverse theory) to the methodology of geophysics: All important aspects of the last few decades of seismology.

But perhaps the most important change for seismology since 1960 was, as for most of the earth sciences, the change in our picture of the Earth created by sea-floor spreading and plate tectonics. Though most of the data that went into this theory came from nonseismic measurements, earthquakes did play a role in two ways. The first was through oceanic seismicity: The more accurate epicenter locations got, and the smaller the magnitude threshold became, the greater the extent to which oceanic earthquakes appeared to occupy only a very narrow and continuous zone along the ocean ridges. The match between this narrow belt of earthquakes and (in some places) a deep median rift helped to focus attention on these narrow zones. The second contribution, especially important for the development of plate tectonics, came from focal-mechanism studies. The debate between single-couple and double-couple mechanisms was settled in 1964 by the demonstration that only the latter was compatible with a dislocation source (first applied to earthquakes by A.V. Vvedenskaya in 1956), and the WWSSN data made possible much more reliable solutions, for smaller earthquakes, with much less effort. Awareness of sea-floor spreading stimulated a study of the mechanism of oceanic earthquakes, which showed that oceanic fracture zones behaved as transform faults, connecting segments of spreading ridge. On a much larger scale, the first published paper suggesting plate tectonics showed that slip vectors of earthquakes around the North Pacific were consistent with the rigidity of this large area. This emphasis on earthquakes as indicators of motion rather than stress rapidly became the norm: only ten years from the time when focal mechanisms were difficult to estimate and confusing to interpret, they had become a routine tool for elucidating tectonics. Indeed, the largest effect of plate tectonics on seismology was to integrate earthquake occurrence (in many areas at least) with other evidence of deformation in ways not done before: Seismicity was finally felt to have been explained, not just described. This was perhaps most true for deep earthquakes: Though the physics of such deep sources was not resolved, the concept of subduction zones changed deep shocks from something that just happened to occur in some places to a consequence of the geometry and history of plate motion.

These conceptual breakthroughs gave a sense that what was going on at the earthquake source was far better understood than before. This, and the increasing level of damage earthquakes produced in a more urbanized world (in which growth has outpaced applications of seismically resistant construction), has created a steadily stronger desire to apply seismology to problems of seismic hazard. One consequence of this was the construction of many local seismic networks, to detect smaller earthquakes and so improve the description of seismicity. Most such networks use telemetered data, a technique first applied by P.G. Gane and others in 1949 to a network for studying rock-bursts in South Africa. The increased interest in hazard, and the increased understanding of seismicity, created new interest in the possibility of earthquake prediction. Prediction studies (and the problem of discriminating earthquakes from explosions) have made studies of the earthquake source, and the mechanics of rock deformation associated with it, into a major part of the seismology of the last forty years, though earthquake prediction belongs to the future, not the history, of seismology.²¹

Acknowledgments

I should like to thank Ben Howell, Carl Kisslinger, S. Miyamura, Carl-Henry Geschwind, David Oldroyd, Frank Evison, Jim Dewey, Bruce Bolt, Teruyuki Kato, Niko Shimazaki, Naomi Oreskes, Robin Adams, Marta Hanson, and R.E.W. Musson for comments, corrections, and additional material—and I apologize for any errors that remain.

Editor's Note

The numbered footnotes and bibliography are given on the attached Handbook CD under the directory \01Agnew. Readers are encouraged to read: Chapter 2, Historical View of Earthquake Engineering, by Housner; Chapter 3, The Jesuit Contribution to Seismology, by Udias and Stauder; Chapter 4, International Seismology by Adams; and Chapter 79 on centennial national reports to IASPEI, especially from Germany, Japan, Russia, the United Kingdom, and the United States, edited by Kisslinger. Biography of many persons mentioned in this chapter is given in Chapter 89, Biography of Notable Earthquake Scientists and Engineers, edited by Howell.

Historical View of Earthquake Engineering¹

G.W. Housner

California Institute of Technology, Pasadena, California, USA

1. Introduction

Earthquake engineering is a 20th-century development, so recent that it is yet premature to attempt to write its history. Many persons in many countries have been involved in the development of earthquake engineering and it is difficult, if not impossible to identify the contributions of each. Many advances in the subject are not well-documented in the literature, and some of the documentation is misleading, or even incorrect. For example, in some instances, earthquake requirements were adopted in building codes but were not used by architects and engineers. And in other instances earthquake design was done by some engineers before seismic requirements were put in the code. A history of earthquake engineering written now could not present a satisfactory account because of poorly documented facts and, in addition, there are still many people that remember relevant information and would be severe critics of a history. To write an acceptable history, it is necessary to wait till most of the poorly known facts have disappeared from memory and literature, then, with a coherent blend of fact and fiction, history can be written.

Although 1984 is too soon to write a definitive history, it is an appropriate time for a historical view of earthquake engineering development to see where we were, where we are now, and where we are going. In this regard, it is interesting to compare the Eighth World Conference with the First World Conference on Earthquake Engineering. In 1956, the 50th anniversary of the San Francisco earthquake, the First World Conference was held in the city of Berkeley, California. It is indicative of the very recent development of earthquake engineering that many of those pioneers who attended the first conference are also present, 28 years later, at the eighth conference. It is gratifying to see that the attendance at

8WCEE is more than 10 times as large as the number attending 1WCEE. In the Preface to the Proceedings of the First Conference, the President of EERI said “The World Conference on Earthquake Engineering was originated and planned by EERI for the purpose of (1) observing by an appropriate technical meeting the 50th anniversary year of the destructive San Francisco earthquake of 1906 and, (2) bringing together the scientists and engineers from major seismic areas of the world in order that their knowledge of earthquakes and developments in the science and art of earthquake-resistant design and construction might be pooled for the benefit of all mankind.” And this still represents the purpose of the eighth conference. However, a big change has occurred in the number of papers presented. The Proceedings of the First Conference had 40 papers and the Proceedings of the Eighth Conference contain 844 papers. This 20 times increase in the number of persons seriously studying earthquake engineering is indicative of the increased importance of the subject in the seismic countries of the world. The authors in the First Conference came from 11 countries and the authors in the Eighth Conference came from 42 countries. Very few seismic countries are not represented at the 1984 Conference and this indicates that there are few seismic countries that are not actively trying to protect against destructive earthquakes, and this is a great change from the situation in 1956.

2. Early Days of Earthquake Engineering

In viewing the early days of earthquake engineering, it is not appropriate to consider developments in pure seismology but, rather, restrict consideration to developments which were made by engineers or which have a special relevance to earthquake engineering. It is surprising to learn that in the early days the most prominent men in earthquake engineering were almost all

¹See Editor's Note.

natives of England, a country of low seismicity. This can be attributed to the Industrial Revolution, in which England was a pioneering country. The intellectual excitement associated with rapid developments in all of engineering between the years 1700–1900 attracted the attention of many able men and some developed an interest in earthquakes. Robert Hooke (1635–1703), the discoverer of Hooke's Law, which is well-known in engineering, gave a series of lectures at the Royal Society in 1667–68 which were published in book form in 1705 with the title "Lectures and Discourses of Earthquakes and Subterranean Eruptions." This was before the days of earthquake engineering and Hooke was actually considering geological matters when he argued that the raising of sub-aqueous land into mountains was caused by earthquakes, so it might be said that Hooke took the first step along the path that led to the theory of plate tectonics. Also, Thomas Young (1773–1829), of Young's modulus, in his book "Lectures on Natural Philosophy," Vol. 2, 1807, gave what appears to be the first European bibliography of earthquake publications. It is interesting that both Hooke and Young, who are so well known by engineers, should have studied earthquakes, though in those early days it was premature to think about earthquake engineering.

In the 19th century, a number of English engineers developed a keen interest in earthquakes, including Robert Mallet (1810–1881), a civil engineer, John Milne (1850–1913), a mining engineer, James Ewing (1855–1935) and Thomas Gray (1850–1908), both mechanical engineers. In the last century no distinction was made between seismology and earthquake engineering. In fact, the word "seismology" derived from the Greek work "*seismos*" (= shaking), was invented by the engineer Robert Mallet and covered all the various interests in earthquakes: earthquake occurrence, ground shaking, earthquake damage, etc. It seems that the name "seismology" (= shake-knowledge) originally designated what we would call earthquake engineering, and it was only during later developments that the name came to designate the studies of the nonengineering aspects of the subject. Robert Mallet also coined the terms "epicenter," "seismic focus," "isoseismal line," and "meizoseismal area."

Robert Mallet published his first paper, "On the Dynamics of Earthquakes" in the Transactions of the Irish Academy, Vol. 2, 1848. In this paper he discusses earthquake effects and considers seismic waves and tsunamis, and he also describes his invention of the electromagnetic seismograph (see Fig. 1). This instrument sat at rest till it sensed the arrival of the seismic waves which activated it and the response of the instrument was recorded on a rotating drum. Mallet did not build such an instrument but a modified seismograph along these lines was built in 1855 by Luigi Palmieri (1867–1896) in Naples, Italy which actually made some earthquake records. Mallet also invented the "rocking blocks" (or falling pins) intensity meter, a form of which for many years was used by the construction industry to measure the intensity of ground motion generated by blasting; and he also compiled a seismic

map of the world which was in use for many years. Mallet also studied the destructive Naples earthquake of 16 December 1857 and wrote a detailed report which included carefully drawn isoseismal lines. He also compiled a 600-page catalog of earthquakes which he said was the "first attempt to complete a catalog that shall embrace all recorded earthquakes." Robert Mallet, I believe, can be called the Primeval Earthquake Engineer.

Milne, Ewing and Gray (Thomas Gray later emigrated to the United States and from 1888 to 1908 was professor of engineering mechanics at Rose Polytechnic Institute in Indiana) developed an interest in earthquakes while teaching at Imperial College of Engineering in Tokyo (later merged into Tokyo University). In addition to studying earthquake damage and other phenomena, they were pioneers in the design and construction of sensitive seismographs and the study of the seismograms. The work of these men, together with Japanese seismologists such as Seikei Sekiya (1855–1896), the world's first officially appointed professor of seismology, and Fusakichi Omori (1868–1923) led to modern seismology. The Seismological Society of Japan was organized by these men in 1880 and this first earthquake society was the forerunner of the many National Societies of Earthquake Engineering that make up the International Association for Earthquake Engineering.

In the latter part of the 19th century and the early part of the 20th century, some large and important earthquakes occurred that aroused the interests of engineers and seismologists and marked an important phase of earthquake engineering. These were the 1891 Mino-Owari, Japan; the 1906 San Francisco, California; and the 1908 Messina, Italy earthquakes. The Mino-Owari earthquake left a prominent fault scarp which is still shown in books on seismology and the San Francisco earthquake focused attention on the San Andreas fault and its displacement. Although these two large earthquakes received worldwide attention, the time was not yet ready for earthquake engineering. In his 1907 ASCE paper "The Effects of the San Francisco Earthquake of 18 April 1906 on Engineering Construction," Professor Charles Derleth said "An attempt to calculate earthquake stress is futile. Such calculations could lead to no practical conclusions of value." Engineering thinking was still based in a static world and dynamics seemed yet to be unthinkable. Despite the fact that in 1906 California had a small population with no great cities, the damage caused by the earthquake was \$10–20 billion (1980) though the number of deaths was only about 1000. This did not shock engineers into developing earthquake engineering. In 1908, however, a large earthquake devastated the city of Messina, Italy and surrounding area, with a loss of life of 83 000, and this disaster was responsible for the birth of practical earthquake design of structures.

It appears that prior to 28 December 1908 engineering thinking was not ready for grappling with the engineering design of structures to resist earthquakes. In most seismic regions, the common type of construction was masonry

FIGURE 1 Drawing of Robert Mallet's proposed seismograph (1848). The seismic elements, two horizontal and one vertical, are tubes of mercury which are excited into oscillation by the earthquake. The oscillation of the mercury makes and breaks an electric circuit and this activates a spring-loaded solenoid to press a pencil against a rotating drum, thus recording the time of making or breaking the circuit. This would give some information about the oscillations of the mercury.

buildings, low in height. At that date, the use of reinforced concrete, and the use of structural steel, was still in its infancy, and the education of engineers was not of a type to encourage thinking about earthquake forces and stresses.

3. Messina, Italy Earthquake of 28 December 1908

As the population of the world increases, the number of structures at risk also increases, and the number of people exposed to earthquake hazards increases. This leads to the possibility of great disasters. The 83 000 death toll of the Messina earthquake was the greatest number ever from a European earthquake. Even the famous 1775 Lisbon, Portugal earthquake had fewer deaths (60 000). The government of Italy responded to the Messina earthquake by appointing a special committee composed of nine practicing engineers and five professors of engineering to study the earthquake and to make recommendations. The report of this

committee appears to be the first engineering recommendation that earthquake-resistant structures be designed by means of the equivalent static method (%g method). This portion of the report appears to have been the contribution of M. Panetti, Professor of Applied Mechanics in Turin, and he recommended that the first story be designed for a horizontal force equal to 1/12 the weight above and the second and third stories to be designed for 1/8 of the building weight above. He stated that the problem is really one of dynamics which, however, is so complicated that it is necessary to have recourse to a static method. Also, in 1909, A. Danusso, Professor of Structural Engineering at Milan, won a prize with his paper, "Statics of Anti-Seismic Construction." The method recommended by Panetti and explained by Danusso, gradually spread to seismic countries around the world. First it was used by progressive engineers and later was adopted by building codes. Until the 1940s it was the standard method of design required by building codes. In Japan, the method was applied successfully to reinforced concrete buildings by Professor Tachu Naito prior to the 1923 Tokyo earthquake and, in the late 1920s, it was applied by

Professor R.R. Martel in the design of a 12-story steel-frame building in Los Angeles. Following the Tokyo earthquake the static method of design with seismic coefficient of 10% was adopted by the Japanese building ordinance and, following the 1933 Long Beach earthquake, the city of Los Angeles adopted the method with a coefficient of 8%. On 1 January 1943, the City of Los Angeles changed its earthquake requirements so that the seismic coefficient varied over the height of the building and was also a function of the total height (i.e., the period of vibration). This was the first time that the seismic requirements of a building code took into account the flexibility of a building as well as its mass; and these requirements were based on dynamic analyses of structures, carried out by R.R. Martel and his students, under research grants made by the Los Angeles County Department of Building and Safety.

The 1923 Tokyo earthquake was also responsible for the establishment of the Earthquake Research Institute at Tokyo University with an eminent engineer, Professor Kyoji Suyehiro, as the first director. This was the first research group formed to study earthquake engineering and seismology.

4. Recording and Analyzing Strong Earthquake Shaking

The recording of earthquake ground accelerations was often recommended by engineers who studied the problem of designing for earthquakes, including John Milne, Kyoji Suyehiro, R.R. Martel and others. However, it seems that prior to 1925 the technology of seismic instruments was not adequate to building strong-motion accelerographs and even in the later 1920s the mental and financial inertia was too great for an accelerograph to be developed. We owe the first accelerographs to the eminent engineer John R. Freeman (1855–1932) who became interested in earthquakes in 1925 at the age of 70, and who attended the 1929 World Engineering Conference in Tokyo where he met and became friends with Martel and Suyehiro. He immediately understood the need for a strong-motion accelerograph and strongly recommended to the Secretary of Commerce that such an instrument should be designed and constructed. On 11 March 1930, Secretary Lamont, an engineer, stated in a letter to Freeman that it would be done. The first accelerographs were installed by the Seismological Field Survey of the US Coast and Geodetic Survey in late 1932, just in time to record the strong ground shaking of the destructive 10 March 1933 Long Beach earthquake. This was a most important step in the development of earthquake engineering. For the first time engineers could see the nature of strong ground shaking: the amplitude of motion, the frequency characteristics, and the duration of shaking. These were items of great interest and they cleared up much confusion, as the literature prior to 1933 contained many erroneous estimates of these quantities. We, who live in 1984,

can hardly conceive of the difficulty of estimating these quantities 100 years ago when the world had not yet moved into the modern age. For example, in the Transactions of the Seismological Society of Japan a paper by J. MacGowan on “Earthquakes in China” describes the earthquake of 12 June 1878 which occurred near Suchow, and he said that it was reported that in Suchow the “shaking was felt for the space of time taken in swallowing 1/2 bowl of rice.” At the time of the First World Conference in 1956, fewer than 70 strong-motion accelerographs were installed in the world, and at that time, few destructive earthquakes occurred close to an accelerograph. It is significant that now most seismic countries have installed networks of accelerographs and that important records are being obtained in many countries. We now have a much better understanding of earthquake ground motions and their effects. In addition, many accelerographs are now installed on structures to record their motions during earthquakes, and these have demonstrated the dynamic responses of multistory buildings, bridges, dams, etc.

The development of computers, first the analog type and then the digital type, was very important for earthquake engineering. These made possible the practical analysis of accelerograms, for without computers the analysis was exceedingly slow and laborious. Computers made possible the development of the response spectrum of earthquake motions and the design spectrum which have played important roles in earthquake engineering and have been adopted in other branches of engineering also. Computers have also made possible the calculation of the dynamic response of structures to earthquake ground shaking and this has greatly clarified our understanding of structural dynamics. We are now able to make dynamic analyses of complex structures. The finite element method of analysis has also been an important development for earthquake engineering. The widespread installation of strong-motion accelerographs, together with the development of powerful computers, has provided large amounts of data and this poses problems of data acquisition, data analysis, data storage, data retrieval, and also data understanding.

In retrospect, it can be seen that in the last twenty years earthquake engineering has been strongly influenced by the implementation of major projects, such as: nuclear power plants, high-rise buildings, major dams, offshore oil drilling platforms, longspan bridges, LNG storage tanks, etc. The large cost of these projects and the need for a high degree of safety required a level of earthquake analysis and design much higher than for ordinary structures. As a consequence, the development of earthquake engineering was accelerated by the needs of these special projects.

5. Development of Building Codes

Special structures such as high-rise buildings, major dams, LNG storage tanks, etc., because of their critical importance are

usually analyzed and designed by making use of the latest research developments. On the other hand, ordinary structures which compose the bulk of modern construction are usually designed according to the requirements of a building code. Because the code is a legal document that specifies a minimum level of design that must be attained by structures, and because it has a large socio-economic impact, substantial changes in code requirements are made slowly and cautiously. In addition, because the building code affects so many agencies, groups, individuals, etc. there is a great inertia against change and developments in the building code tend to lag behind developments in research. In many instances, needed changes in the code are deferred until the occurrence of a destructive earthquake; for example, 1908 Messina, Italy; 1923 Tokyo, Japan; 1933 Long Beach, California; 1971 San Fernando, California; 1976 Tangshan, China. The development of the building code thus illustrates the development of applied earthquake engineering for ordinary construction. The development of earthquake requirements in the Los Angeles city building code is a good example. Until 1933, earthquake design was not required; then the deaths and damage caused by the M 6.3 10 March 1933 Long Beach earthquake produced the requirement that every building must be designed for a minimum horizontal force of 8% of the weight, without consideration of height, shape, rigidity, material of construction, use, foundation condition, or degree of seismic hazard. The code was changed at intervals and the requirements of the present code do take into account the foregoing items. In addition, following the 1971 San Fernando earthquake a requirement was added that every structure over 160 ft in height shall have strength sufficient to resist the effects of earthquakes as determined by a dynamic analysis, and that this analysis shall be based on the ground shaking prescribed by a soil-geology-seismology report. The 1984 Los Angeles code is a great improvement over the 1934 code. The past fifty years, which is a short time in the life of a building code, have seen great improvements in building codes worldwide; and these improvements will certainly reduce loss of life and property damage in future earthquakes. During the past 100 years, over one million persons have been killed by earthquakes and it is the responsibility of earthquake engineers to ensure that this does not happen again during the coming 100 years. Earthquake engineers should examine the building codes in their countries to make sure that the requirements are indeed appropriate to the seismic risk.

6. Nontechnical Earthquake Engineering

A history of earthquake engineering should also examine the development of thinking in governmental agencies, and the thinking of the public. Relatively recent developments in some cities, such as Tokyo and Los Angeles, include improved thinking in city government agencies. National and state government

agencies are also giving earthquake hazards increasing consideration. In some regions, earthquake preparedness measures are being taken to reduce the risk of life and property, to prepare to handle the emergency when the coming earthquake occurs, and to mitigate the effects of future earthquake disasters upon the functioning of the city and the impact on the public. These are noteworthy developments in nontechnical earthquake engineering, if we define earthquake engineering broadly to encompass all nontechnical, as well as technical, efforts directed toward minimizing those harmful effects of earthquakes.

Public understanding of earthquake risk is also important. A great advance in earthquake knowledge possessed by the average citizen has occurred over the past thirty years, and this has resulted in greater support for earthquake preparedness measures. However, even today, the average citizen has a relatively poor understanding of earthquake risks and earthquake engineering benefits. Because of the way the news media handle the topic of earthquakes, the public tends to oscillate between excessive alarm and excessive complacency. Improvements need to be made in public education about earthquake risks and earthquake preparedness, beginning with children in the public schools.

7. Summary

Over the past fifty years, there has been remarkable progress in earthquake engineering research. Knowledge of earthquake ground shaking and earthquake vibrations of structures has undergone a great expansion. Advances in methods of dynamic analysis enable the earthquake response of planned structures to be calculated. Experimental research is providing valuable data on the physical properties of structures and structural elements. The increase in number of research papers published each year is indicative of the progress being made. We have now attained a good understanding of the elastic earthquake response of typical buildings. However, there are many special structures, industrial equipment, etc. whose earthquake survival is important and which need special earthquake engineering research. Also, the question of "maximum credible" or "maximum probable" earthquake needs to be better defined by research, as well as the question of appropriate level of design of structures for such events of low likelihood. And more research needs to be done on designing for controlled damage in the event of large, infrequent earthquakes.

Building codes have also undergone a big development over the past fifty years. The 1984 building codes now handle the earthquake design of structures in a much improved way over the 1934 building codes. However, the real test of a building code comes when a city experiences strong ground shaking. Actual structures, as distinguished from ideal structures, are so complex that their behavior must be tested by strong shaking to establish their adequacy or to reveal inadequacies. In 1984,

conclusive tests of modern building codes have not yet been made. It is important that, in the future, destructive earthquakes be studied with a view to assessing the adequacy of the building code. Many earthquakes have been inspected in the past, and many reports have been written, but too few valuable conclusions have been deduced. Earthquake engineers should prepare ahead of time to learn from coming destructive earthquakes. Thought must be given ahead of time to what can be learned, and preparations should be made ahead of time for the learning process.

When the earthquake comes, everything connected to the Earth either directly, or indirectly, will be shaken. All those items whose survival is very important must be given special attention in design and construction to insure against unacceptable damage, and structures must also be designed to protect against injury and loss of life. An earthquake disaster requires three things: (1) the occurrence of an earthquake sufficiently large to produce strong ground shaking; (2) the earthquake must be sufficiently close so that a city experiences strong shaking; and (3) the city must be unprepared for an earthquake, with numerous weak buildings. When these three coincide there is a disaster. Such coincidences were not uncommon in the past (see Table 1, for example).

The list in Table 1 is incomplete; many other destructive earthquakes occurred where death tolls numbered in the

thousands. Disastrous earthquakes can be expected also in future years, for many existing cities are poorly prepared to resist earthquakes. In addition, inasmuch as the world's population is increasing by 80 million persons per year and cities are correspondingly expanding, the earthquake risk is increasing. In coming years large earthquakes can be expected to occur close to large cities more frequently than in the past. It is the responsibility of earthquake engineers to insure that the new construction in these cities is earthquake resistant, and that the greatest hazards from old weak buildings are eliminated. The discipline of earthquake engineering is now entering its golden age with greatly expanded knowledge and capabilities, but it is also facing important new problems, for in coming years there will be construction of large, complex, and costly structures, industrial facilities, and socioeconomic projects which the earthquake engineer must make safe against destructive ground shaking.

The Jesuit Contribution to Seismology

Agustín Udías

Universidad Complutense, Madrid, Spain

William Stauder

Saint Louis University, St. Louis, Missouri, USA

1. Introduction

The contribution to seismology of the Society of Jesus as an institution through its colleges and universities, and through its members as individual scientists, forms an important chapter in the history of this science. This is especially so in the early years of its development. Several papers have described in part the work of Jesuits in seismology: Sánchez Navarro-Neumann (1928, 1937), Heck (1944), who limits himself to American Jesuits, and the interesting but short summaries of Linehan (1970, 1984). No recent or comprehensive work, however, exists on the topic. Recently, moreover, many Jesuit seismographic stations have been closed and the number of Jesuits actually working in seismology has been greatly reduced. To a certain extent, apart from a very few academic departments and research institutes associated with Jesuit universities, it can be said that this is a chapter which is coming to a close. The interest of Jesuits has moved in other directions and it is not likely that seismology will become again an important aspect of the work of individual Jesuits as it was in the past. For this reason we feel that it will be of interest to present an overall picture of the extent of the Jesuit involvement in seismology.

It may be intriguing to some that a religious order dedicated so much effort to a science like seismology. From the very early years of its foundation in the 16th century by Ignacio de Loyola, the Society of Jesus dedicated itself primarily to educational work through its many colleges and universities. From the beginning of these institutions, science was an important subject in the curriculum. A key figure in this development was Christopher Clavius (1537–1612), Professor of Mathematics in the Collegio Romano. Clavius was instrumental in incorporating a serious program of mathematics, astronomy, and natural sciences not only in his own college but also in all Jesuit colleges and universities (MacDonnell,

1989). Secondly, in the 17th and 18th centuries a number of astronomical observatories were established in these institutions. In a number of these, meteorological observations also were made. Finally, in a particularly notable page of this history, Jesuits were appointed Directors of the Astronomical Observatory in Beijing, China (Udías, 1994). This tradition forms the background of modern Jesuit scientific work. Since the middle of the 19th century, as many as 40 geophysical observatories were created by Jesuits around the world and in many of these seismological stations were installed (Udías and Stauder, 1991).

As a science, seismology is relatively young. Davison (1927) dates its beginning to 1750 with the Lisbon earthquake and the work of John Michell (1724–1793). Although pendulums were used to detect the ground motion due to earthquakes at the beginning of the 19th century, the earliest seismographs were those developed in Italy by Luigi Palmieri (1807–1896) in 1855 and by Timoteo Bertelli (1826–1905) in 1872. Seismographs with continuous recording were developed in Japan from 1881 to 1882 by John Milne (1850–1913) and Thomas Gray (1850–1908). One of the first studies of earthquakes is that of Robert Mallet (1810–1881), who investigated the Naples earthquake of 1857 (Davison, 1927). The first record of a long-distance earthquake is a fortuitous recording of an earthquake in Japan by pendulums set up in Potsdam in 1889 by E. A. von Reuber-Paschwitz (1861–1895). From these dates and events, seismology began to develop not only as a study of the nature of earthquakes but also, through the analysis of the seismic waves, as a method to investigate the structure of the interior of the Earth.

A series of circumstances and interests involved Jesuits in the development of this new science from its inception. This interest, certainly, was consonant with the tradition of Jesuits in science dating from the 16th century, which developed, as

has been mentioned, out of their work in colleges and universities. The character of seismology as a public service to mitigate the destructive effects of earthquakes was another influential factor. Especially in undeveloped countries, Jesuits were in many instances the first to install seismographic stations and to carry out seismicity and seismic risk studies.

Two trends may be distinguished in this involvement of Jesuits in seismology. In the United States, emphasis was on the cooperation of Jesuit institutions in the establishment of seismographic stations organized first as the Jesuit Seismological Service and subsequently as the Jesuit Seismological Association. In other countries, especially in mission lands, the movement developed out of the activity of individual institutions in establishing seismic observatories, usually as a complement to the recording of other geophysical data.

2. Jesuit Seismographic Stations

Table 1 presents a list of 38 seismographic stations installed and maintained by Jesuits. In each case dates of the installation of different types of seismographs are given (OM indicates “own manufacture”). The distribution by continents is as follows: Europe 6, Asia 4, Africa 2, Australia 1, North America 18, and South America 7 (Fig. 1). Most of these stations were founded before 1920, and many ceased operation in the 1960s and 1970s. At present, there are only 8 functioning regularly. Initially, the preferred instruments were Wiechert and Mainka mechanical seismographs, and later, Galitzin–Wilip and Sprengnether electromagnetic instruments. In 1962, 10 Jesuit stations became part of the 125-station global World Wide Standard Seismographic Network (WWSSN) supported

by the US Government. Of these two, one in Colombia and the other in Bolivia, were later upgraded to become Seismological Research Observatory (SRO) and High Gain Long Period-Adapted Seismological Research Observatory (HGLP-ASRO) stations, respectively.

The first seismographic station installed by Jesuits was about 1868 in the Observatory of Manila. This consisted of two pendulums, one vertical the other horizontal, and were what we would today call seismoscopes. They were designed by Juan Ricart, Professor of Sciences at the Manila Jesuit College. They functioned intermittently until 1877 when regular, continuous-recording instruments were installed. After the Manila earthquakes of 1880, which were recorded on the old seismographs and studied by Federico Faura (1847–1897), the station was better equipped with Cecchi, Bertelli, and Rossi seismographs made in Italy. Additional stations were

installed at other points of the Philippines, namely at Baguio, Ambulong, Butuam, Tagaytay, and the island of Guam (Saderra-Masó, 1895, 1915; Su, 1988). Unfortunately, all seismographic records were lost in the destruction of the observatory during World War II. The continuous catalog of Philippine earthquakes, however, was salvaged and was published shortly after the war by Repetti (1946). After the war, new seismographs were installed in Manila, Baguio, and Davao. The last two sites became WWSSN stations in 1962.

The first seismograph installed by Jesuits in Europe was a seismoscope made by Giovanni Egidi (1835–1897) and installed in the meteorological observatory in Tuscolano, Frascati, Italy, founded in 1868 (Egidi, 1888). An important station was installed in 1902 in Granada, the most seismically active region of Spain. Due to a lack of funds most seismographs were made patiently under the direction of Manuel

FIGURE 1 Map showing the location of Jesuit seismographic stations.

Sánchez Navarro-Neumann (1867–1941), who reproduced with some improvements the Omori, Wiechert, and Galitzin seismographs (Sánchez Navarro-Neumann, 1928). In Ireland, William J. O’Leary installed the first seismograph, also of local design, at Mungret College in 1908. In 1916 it was moved to Rathfarnham Castle, where it was in operation until 1961. This was an inverted pendulum suspended by steel wires with a mass of 600 kg recording on smoked paper on two drums (Murphy, 1995). In the Ebro Observatory, Spain, a seismological station has functioned continuously from 1904 to the present. At Stonyhurst, England, the station operated from 1908 to 1947. A seismographic station was also established by Jesuits on the Island of Jersey, operating from 1936 to 1979.

Very early, in 1899, Jesuits installed a seismographic station in Madagascar using instruments of Italian design. In 1927 a three-component Mainka seismograph was installed. This station operated under Jesuit supervision until 1967 and may have been one of the earliest seismographic stations in Africa. In 1904 Jesuits installed an Omori seismograph donated by the Japanese government in the observatory of Zikawei. This may have been the first such station in China. Updated with Wiechert and Galitzin–Wilip instruments in 1909 and 1932, respectively, Zikawei continued as a first-class station up to the time the Jesuits were expelled from China in 1949 (Gherzi, 1950). In Ksara, Lebanon, seismographs were installed in 1910. This was an important station due to lack of stations in the Middle East. It operated uninterruptedly until 1979 with Wiechert instruments. In Australia, the Jesuit seismographic station of Riverview was initiated in 1909 with Wiechert instruments. In 1962 it became a WWSSN station and operated until 1985. For many years this was the best known and best equipped station in Australia (Drake, 1980; Doyle and Underwood, 1965).

At the 2nd General Assembly of the International Seismological Association, Manchester, 1911, a resolution was passed

recommending that the Jesuits install a seismic station in the central part of South America. In response to this recommendation, a seismological station was installed in 1913 at La Paz, Bolivia, with the name of Observatory de S. Calixto, by Pierre M. Descotes (1877–1964), with instruments of local design. In 1930, the station was upgraded with Galitzin–Wilip seismographs. From 1964 to 1993, the station was directed by Ramón Cabré. The Observatory of S. Calixto has been one of the most reliable stations in South America (Cabré, 1988; Coenraads, 1993). The first seismograph in Colombia was installed by Jesuits in 1923 in Bogotá. In 1941 the Instituto Geofísico de los Andes Colombianos (today the Instituto Geofísico, Universidad Javeriana) was founded by Jesus E. Ramirez (1904–1983). This soon became one of the best seismological research institutions in South America (Ramirez, 1977; Goberna, 1988). In 1962, the stations of La Paz and Bogotá became WWSSN stations. Later La Paz became an HGLP-ASRO station (1972) and Bogotá became an SRO station (1973). This upgrade is a clear recognition of the work done by Jesuits in these two stations.

Other Jesuit seismographic stations in Cuba and Chile functioned only a few years. In 1940 a seismographic station was installed in St. George’s College, Kingston, Jamaica, dependent on Weston Observatory. In Montreal, Canada, a seismographic station was installed in 1952 (Buist, 1983). The Montreal station was a modern station with WWSSN-type instruments. It was the last new station installed under direct Jesuit auspices. Maurice Buist was its director for 31 y until his retirement in 1983. In Ethiopia, Haile Salassie invited the Jesuits to undertake the administration of the National University in Addis Ababa. Although not a Jesuit station in the strict sense, the associated Geophysical Observatory of Addis Ababa was directed by the Canadian Jesuit Pierre Gouin from 1957 to 1978. In 1962, a WWSSN seismographic station was installed.

3. The Jesuit Seismological Association

The history of the work of Jesuits in seismology in the United States is linked to the Jesuit Seismological Association (Macelwane, 1926, 1950). The first Jesuit to install a seismograph in the United States was Frederik L. Odenbach (1857–1933) in 1900 at John Carroll University, Cleveland, Ohio, with two seismoscopes of his own design. In 1908 Odenbach conceived the notion that the system of Jesuit colleges and universities distributed throughout the United States offered an opportunity to establish a network of similar seismographic stations. In 1906 the International Seismological Center had been established in Strasbourg, France, where data were centrally reported and epicenters determined. Odenbach envisioned a network of Jesuit stations that could contribute significant data to this international enterprise.

Odenbach sold the presidents of the colleges and universities and the American Jesuit Provincial Superiors on the idea. In 1909 sixteen identical horizontal Wiechert seismographs of 80 kg mass were purchased in Germany and were distributed to 15 colleges in the United States and one in Canada. A typical station was that of Georgetown (Fig. 2). These stations formed the Jesuit Seismological Service. Individual stations were to process their own seismograms and send the readings to the Central Station in Cleveland. The data would then be collated and forwarded to the International Seismological Center in Strasbourg. These stations, in effect, constituted the first seismological network of continental scale with uniform instrumentation.

Many of the first stations, for a variety of reasons, foundered early, and the cooperative effort was never fully established. In 1925 James B. Macelwane (1883–1956) returned to Saint Louis University after completing his doctoral studies at the University of California. One of Macelwane's early efforts was to revitalize the Jesuit seismographic network. The impetus to this came not only from his own interest but also from the urging of scientists of the National Research Council and the Carnegie Institution in Washington, and with the further encouragement of Sánchez Navarro-Neumann of the Spanish Observatory at Cartuja.

Thus, in the summer of 1925 the stations were reorganized into the Jesuit Seismological Association. The 14 member stations are indicated as JSA in Table 1. The Presidents of the Association have been J.B. Macelwane of Saint Louis University, 1925–1956; J.J. Lynch of Fordham University, 1957–1970; and D. Linehan of Weston Observatory, 1970–1986. W. Stauder of Saint Louis University has been President from 1986 to the present.

Saint Louis University became the Central Station in 1925. Through its recently established Department of Geophysics it became a resource for graduate education in seismology for a number of Jesuits who then returned as directors to their own

FIGURE 2 Instruments of the Georgetown seismographic station, about 1920. The Wiechert is on the far right.

institutions. The Central Station assumed as well the responsibility on behalf of the JSA of collecting data from member stations and from other stations around the world and of locating earthquake epicenters and publishing these to the worldwide seismological community. The Central Station continued this service until the early 1960s when, with the advent of computer determination of epicenters, it was discontinued as an unnecessary duplication of the determinations by the US Coast and Geodetic Survey (later by the US Geological Survey) in the United States and by other international agencies.

Most of the JSA seismographic stations continued in regular operation until relatively recent time. Florissant (Saint Louis), Weston, Georgetown, and Spring Hill became WWSSN stations in 1962. At present only Saint Louis and Weston continue as seismological research institutes. Both conduct active research programs and operate regional networks, and are members of IRIS, the Incorporated Research Institutes for Seismology. Saint Louis has installed a broadband station of the IRIS system at Cathedral Cave, Missouri and is deploying other similar broadband stations in the Midwest.

4. Jesuit Seismologists

From 1868, the approximate date of the installation of the first seismograph by the Jesuits in Manila, to the present, many members of this religious order have dedicated their time and efforts to seismology. In this short article it is hardly possible to do more than mention even the most important of them. However, a few words must be said about those that occupy an important place in the history of seismology. We will mention

only the work of past Jesuits, although at present there are still Jesuits actively working in seismology (e.g., L. Drake, presently at La Paz, P. Gouin in Montreal, W. Stauder in St. Louis, S. Su in Manila, R. Van Hissenhoven in Bogotá, and A. Udías in Madrid).

The first Jesuit to be mentioned is Federico Faura, who published a study about the destructive Manila earthquakes of 1880 (Faura, 1880). In the paper he reproduced the records obtained by the instruments (seismoscopes) in the Observatory of Manila. Faura continued his interest in seismology, improving the seismological instrumentation of the Observatory and publishing a seismological bulletin. Beginning in 1877, Giovanni Egidi, director of the Observatory Tuscolano in Italy, collaborated with M.S. De Rossi in the seismological observations that were published in *Bullettino del Vulcanismo Italiano* (Davison, 1927, p. 100).

Two Jesuits contributed very early to the study of the seismicity and seismotectonics of the Philippines and Spain. Manuel Saderra-Masó dedicated himself to the study of the seismicity of the Philippines, interpreting it in terms of seismotectonic lines and relating it to the geological structure of the archipelago in a very early work of this type (Saderra-Masó, 1895; Saderra-Masó and Smith, 1913). M. Sánchez Navarro-Neumann, Director of the Observatory of Cartuja, Spain, compiled the first modern earthquake catalogue of Spain and published numerous studies on the seismicity of that region (Sánchez Navarro-Neumann, 1919). He also published an early paper on the energy in earthquakes (Sánchez Navarro-Neumann, 1915).

The most renowned Jesuit seismologist was without doubt James B. Macelwane (Fig. 3) (Byerly and Stauder, 1958). Macelwane obtained his doctoral degree at the University of California, Berkeley, in 1923, with the first dissertation on a seismological topic in the United States. In 1925 he became the first Director of the Department of Geophysics at Saint Louis University and reorganized the Jesuit Seismological Association. Travel times of seismic waves, the constitution of the interior of the earth, and the nature of microseisms and their relation to atmospheric storms were a few of the topics of his research papers (e.g., Macelwane and Dahm, 1937; Macelwane, 1939, 1946). In 1936 he published the first textbook on seismology in America (Macelwane, 1936). In 1928–29 he was President of the Seismological Society of America and in 1953–56 of the American Geophysical Union. In 1944 he was elected to the National Academy of Sciences. Throughout his career Macelwane took an active part in the committees and commissions of these societies, as well as in projects of the National Research Council and the International Union of Geodesy and Geophysics. He was also always interested in promoting educational programs and in encouraging young geophysicists. For the latter reason, in 1962 the American Geophysical Union created a medal in his honor for recognition of significant contribution to the geophysical sciences by a young scientist of outstanding ability.

FIGURE 3 James B. Macelwane, S.J.

Two Jesuit students of Macelwane deserve to be mentioned. William C. Repetti (1884–1966) studied the interior of the Earth from the travel times of body waves, inferring the existence of several discontinuities in its interior. In 1928 he joined the staff of the Manila Observatory, where he assumed charge of the seismological section. Among other contributions he compiled a catalog of earthquakes of the Philippines (Repetti, 1946). Jesus E. Ramirez (1904–1983) worked on the problem of microseisms and storms, designing a tripartite station system to track the center of tropical hurricanes. In 1941 he founded in Bogotá the Instituto Geofísico de los Andes Colombianos, where he conducted and published a large number of studies of Colombian seismicity (Ramirez, 1967). He was a leading figure in the seismicity of South America.

J. Joseph Lynch (1894–1987) became Director of the Seismographic Station of Fordham University in 1920. This was the beginning of a long career as a seismologist that led to a variety of seismological studies, among them a field study of the Dominican Republic earthquake of 1946. He has left us a lively account of his involvement in seismology over a period of 50 y (Lynch, 1970). Daniel Linehan (1904–1987) was Professor of Geophysics and Director of Weston Observatory for 32 y. A prolific writer in many aspects of seismology, he dedicated himself especially to seismic exploration. In 1950 he carried out, accompanied by Lynch, a shallow

seismic exploration survey under St. Peter's Basilica in Rome for archeological purposes. He participated in three expeditions to the Antarctic, one to the Arctic, and several UNESCO seismological missions in Africa, Asia, and South America. Two other Jesuits participated in separate expeditions to the Antarctic during the International Geophysical Year: Edward Bradley of Xavier University, Cincinnati, and Henry Birkenhauer of John Carroll University, Cleveland.

Of European Jesuit seismologists, Richard E. Ingram (1916–1967), Director of Rathfarnham Castle, Ireland merits mention for his theoretical papers (Ingram, 1963).

Among the different topics in seismology, the study of microseisms attracted the special interest of Jesuit seismologists. We have already mentioned the work of Macelwane and Ramirez, with a first paper in 1935. Probably the first suggestion of the relation between microseisms and storms was made by José Algue (1859–1930), Director of Manila Observatory, as early as 1894 in his study of Philippine Islands typhoons (Deppermann, 1951). Ernesto Gherzi (1886–1976), Director of Zikawei Observatory, published several papers on the relation between microseisms and atmospheric

conditions (Gherzi, 1924). In 1952 a seminar was organized by the Pontifical Academy of Sciences on the problem of microseisms in which Gherzi, Macelwane, and Due-Rajo (Cartuja) participated, along with a select group of other specialists.

Jesuits participated in the early stages of the organization of seismological associations. R. Cirera (1864–1932), first Director of Ebro Observatory, represented Spain as one of two delegates in the second meeting of the International Seismological Conference in 1903 in Strasbourg (Rothé, 1981). Three Jesuits, Berloty (Ksara), Sánchez Navarro-Neumann (Cartuja) and Stein (Vatican) were present at the first General Assembly of the International Association of Seismology in the Hague in 1907. Jesuits have participated actively in the International Association of Seismology and the Physics of the Earth's Interior since its establishment in 1922 as part of the International Union of Geodesy and Geophysics (IUGG).

Jesuits have had a special relation with the Seismological Society of America. One of the 13 participants at the first meeting for its founding in 1906 was Jerome S. Ricard (1850–1930), Director of Santa Clara Observatory, who was elected

FIGURE 4 Participants in the joint meeting of the Eastern Section of the Seismological Society of America and the Jesuit Seismological Association held in St. Louis, 1937. *First row (l to r):* Anthony J. Westland, S.J., Archie Blake, Ernest A. Hodgson, Capt. Nicholas H. Heck, James B. Macelwane, S.J., J. Joseph Lynch, S.J. *Second row (l to r):* J. Emilio Ramirez, S.J., Alphonse R. Schmitt, S.J., Louis B. Schlichter, Alton C. Chick. *Third row (l to r):* H.M. Rutherford, Florence Robertson, Paul Weaver, —?, Victor G. Stechschulte, S.J., Theodore Zegers, S.J. *Fourth row (l to r):* Daniel Linehan, S.J., Albert J. Frank, Arthur C. Ruge, Msgr. Joseph A. Murray, John P. Delaney, S.J., Ross Heinrich.

a member of the first Board of Directors (Byerly, 1964). J.B. Macelwane also served on the Board from 1925 to 1956 and was elected President of the Society in 1928. W. Stauder served on the Board from 1962 to 1967 and was President in 1966. Several Jesuits have been Chairman of the Eastern Section of the Seismological Society of America: J.B. Macelwane, 1926 (first Chairman); J.J. Lynch, 1930; V.C. Stechschulte, 1933; D. Linehan, 1954; V. Blum, 1955; H. Birkenhauer, 1956; and W. Stauder, 1963. For many years the Jesuit Seismological Association met jointly with the Eastern Section. In 1937, for example, at the joint meeting in St. Louis, of 22 participants 9 were Jesuits (Fig. 4); in 1948 at the meeting in Cleveland, of 29 participants 8 were Jesuits; and in 1961 at the joint meeting in Cincinnati, of more than 80 participants 9 were Jesuits.

5. Conclusion

As we have seen, Jesuits contributed to organizational, experimental, and theoretical aspects of seismology. Their principal contribution has been providing seismological data for research into the constitution of the Earth and the processes of generation of earthquakes. To accomplish this more effectively, Jesuit stations regularly endeavored to update the quality of their instrumentation (Table 1). This was particularly of significance in the early times, between 1910 and 1960, when the number and quality of seismological stations worldwide was rather limited. Jesuit stations in South America, Africa, and Asia were particularly important in those early times. In some instances, they were the only reliable stations in a region for many years. Establishment of modern national seismological networks and research institutions has made their work no longer necessary and explains the closing of many Jesuit stations.

The reporting of data has been a service of Jesuit observatories. Although many of the stations have been closed, those still active keep up this tradition. More and more, though, the contributions of Jesuits to this now very modern and developed science are through the research centers, principally Saint Louis University, Weston Observatory, Instituto Geofísico (Bogotá), Observatorio de S. Calixto (La Paz), and Manila Observatory. There are also contributions by individual Jesuits associated with Jesuit stations or working in or with other institutions or associations. They have continued to play an important part in the development of the theory of plate tectonics, in the study of the deep constitution of the Earth and of the mechanism of earthquakes, and in the earthquake hazard reduction programs of their various national efforts and cooperative international initiatives. They do indeed stand even today in the tradition of the early Jesuit pioneers.

In order to preserve a recognition of the contribution of Jesuits to this science, in 1989 the Jesuit Seismological Association approached the Eastern Section of the Seismological

Society of America with the offer to fund the establishment of an award to honor an individual who has contributed notably to observational seismology. The Eastern Section accepted the proposal in 1991. The award is now conferred annually and bears with it a plaque and a small monetary prize.

International Seismology

R.D. Adams

International Seismological Centre, UK

1. Introduction

Among the sciences, seismology is probably that which benefits most by people working together, and from the very beginning of our science this need was recognized. The advent of instrumental recording late in the 19th century made the need for such cooperation even more evident, and it was necessary for seismologists to work together in two main ways. On the practical side it is necessary to exchange details of earthquake recordings made in different countries to establish the earthquakes' positions with reliability, and it is also important for seismologists to meet together to plan activities and discuss results.

This account gives particular emphasis to the early history of the international bodies involved in seismology and global earthquake location and traces their development. Much information is taken from Rothé's (1981) history of the early days of seismology, and there is also much useful and complementary information in Chapter 1 by Agnew and Chapter 88 by Schweitzer and Lee. It is impossible to refer to all international bodies and activities, but it is hoped that those chosen are representative, and there are no major omissions. Fuller details of the organization and activities of many present-day bodies, including their contact addresses, can be found in other chapters of this publication.

2. Historical Developments

2.1 Early Organizations

Early efforts were made by Frenchmen Alexis Perrey and Count Ferdinand de Montessus de Ballore in the second half of the 19th century to make international collections of natural phenomena, including earthquakes, and by this time many national seismological groups had grown up, including those in Germany, Switzerland, Italy as well as in Japan and the United States. In many of these countries instruments were being developed to record earth movement, and the first reported

observation of a teleseism was that made by Rebeur-Paschwitz at Potsdam from a Japanese earthquake in 1889. The time was ripe for international cooperation to develop.

The first serious discussions on international needs of seismology were held under the auspices of the geographers. The Sixth International Congress of Geography, held in London in 1895, acknowledged "the scientific necessity of an international system of stations for the observation of earthquakes," while it was at the Seventh International Congress, held in Berlin in 1899, that Dr G.C.K. Gerland, Professor of Geography at Strasbourg, suggested the establishment of an "International Society of Seismology."

As a consequence, the First International Conference on Seismology was held in Strasbourg, 11–13 April 1901. It was at this meeting that the formal setting up of an International Association of Seismology was discussed in detail. This may be considered as the first meeting of our Association. Professor Gerland presided and the Secretary of the meeting was Dr E. Rudolph, also from Germany. In addition there were members from Austria, Belgium, Germany, Hungary, Italy, Japan, Russia and Switzerland. Gerland was himself in favour of a society of individuals, but the majority wanted an association of states and the German government was asked to make the necessary diplomatic approaches to interested countries.

By the time of the Second International Conference on Seismology, also held in Strasbourg, 24–28 July 1903, twenty countries were officially represented. In addition to those in Europe there were representatives from Argentina, Chile, Congo, Japan, Mexico and the United States.

The International Association of Seismology (IAS) was formally established on 1 April 1904, with 18 member countries, but some others such as Argentina, Austria, Denmark, France, Great Britain, Serbia and Sweden declined or would only join on condition that some changes be made to the constitution.

The first meeting under the new constitution was the Third International Conference on Seismology, at Berlin on 15 August 1905. At this meeting Professor Palazzo from Rome

became President, and the Hungarian Baron von Kövesligethy became Secretary-General. The Association was now firmly established.

2.2 Instrumental Cooperation—Milne's Network

While administrative discussions were progressing for establishing a formal International Association of Seismology, the Englishman John Milne was setting up the first worldwide recording network and analysis centre. Milne had been Professor of Geology and Mining at the Imperial College of Engineering in Tokyo until 1895, when, at the relatively young age of 45, he returned to England and set up a seismological observatory at Shide on the Isle of Wight. While in Japan, he had developed with the help of others a reliable horizontal pendulum seismograph, which was to become the standard instrument of his network. Money was made available from the British Association for the Advancement of Science (BAAS) and from 1899 onwards instruments were installed.

The network grew to a total of about 30 instruments, an international network unrivalled until the World Wide Standard Seismograph Network sponsored by the United States in the 1960s. Milne also received registers of readings from these stations, which from 1899 were published by the BAAS as the *Shide Circulars*. The first circular contains readings from stations at Shide, Kew, San Fernando (Spain), Cape of Good Hope, Mauritius, Cairo, Calcutta, Madras, Bombay, Tokyo and Batavia. The intermediate-period Milne seismographs were not good at recording short-period body waves, and early circulars reported times of the commencement (of "preliminary tremors") and first and second maxima, maximum amplitude and duration. Despite only a very primitive knowledge of travel times, attempts were made at location, which improved as knowledge expanded; from 1907 tables prepared by Zöppritz were available for the main phases. Between 1911 and 1913 the BAAS, of which Milne was the Secretary, published bulletins containing global epicentres derived from readings at the Milne stations for the period 1899–1910. Milne died in 1913, and his work was carried on at Shide under the British Association's Seismological Committee until it moved to Oxford University under Professor H.H. Turner in 1916.

Figure 1 shows a contemporary map of Milne's network in 1899, with the stations shown by their names, and catalogue numbers giving approximate positions of earthquakes.

2.3 International Association of Seismology 1904–1916

Independently of Milne, the newly formed IAS was setting up its own analysis organization in Europe. A Central Bureau was established in Strasbourg, advised by a Permanent Commission. The Bureau was responsible for collecting and analysing station

readings, and published macroseismic and instrumental catalogues for the years 1903 to 1908. Work was also carried out on instrumental development. Naturally, because of their similar aims, rivalry grew up between the Central Bureau at Strasbourg and Milne's centre in Britain; this continued for many decades.

The Association was administered by a Permanent Commission, consisting of the Director of the Central Bureau and one member from each adhering state. Committees were set up to study seismic instrumentation and intensity scales. Further meetings of the Association were held in 1907 (The Hague) and in 1911 (Manchester), at which numerous papers were read, and seismological problems were discussed. The next Assembly was planned to be held at St Petersburg from 30 August to 6 September 1914, but the outbreak of hostilities in Europe at the beginning of August forced its postponement. The Secretary-General, Baron von Kövesligethy, who had travelled to St Petersburg to prepare for the meeting with the President, Prince Galitzin, had to undertake a perilous return journey to Hungary through Sweden.

The international convention setting up the IAS was for only ten years, so independently of the war, the Association lapsed on 1 April 1916.

2.4 Seismology Section of the International Union of Geodesy and Geophysics 1922–1930

Soon after the First World War meetings were held in London and Paris to discuss the organization of international scientific unions. As a result of these, the International Union of Geodesy and Geophysics was created in Brussels in 1919, and was to hold its first General Assembly in Rome in May 1922, with a new Seismology Section meeting for the first time. Immediately before this, in April 1922, a "Dissolution Assembly" of the old International Association of Seismology was held at the Central Bureau in Strasbourg. The Assembly decided to refund all remaining funds to the contributing countries and donate all its records and other scientific documents to the new organization.

The first meeting of the Seismology Section was attended by delegates from 33 countries, who elected Professor H.H. Turner (Great Britain) as President, and Professor E. Rothé (France) as Secretary. There were also decisions to be made about the international responsibility for earthquake location. After Milne's death in 1913, his work had been carried on, first at Shide and later at Oxford, with the support of BAAS. The 1922 meeting in Rome set up the International Seismological Summary (ISS) to continue at Oxford under Professor Turner, to produce the definitive global catalogues from the data year 1918 onwards, under the auspices of IUGG. At Strasbourg, Professor Rothé continued to produce the Bulletins of the Bureau Central International de Séismologie (BCIS) forming a valuable additional source of global earthquake information.

FIGURE 1 Global earthquakes and seismograph stations in 1899, as published by Milne. Numbers refer to earthquakes listed in Milne's catalogue, and show approximate positions. (Originally published in J. Milne (1900) Fifth Report of the Committee on Seismological Investigations, Plate II. British Association for the Advancement of Science, London.)

The Seismology Section held further meetings at Madrid (1924), Prague (1927) and Stockholm (1930), at General Assemblies of IUGG. Professor Turner remained President for these three meetings, but tragically was to die during the last, shortly after giving his Presidential address, in which he had praised the burgeoning seismological activity in the United States, with the US Coast and Geodetic Survey (USCGS) and Jesuit Seismological Association both being extremely active. He also praised the research being carried out in Japan, particularly by Wadati on deep earthquakes.

2.5 International Association of Seismology 1930–1951

During the Stockholm Assembly, sections of IUGG were renamed as Associations, and the name International Association of Seismology was once more adopted. The first meeting

under the new statutes was held in Lisbon in 1933, with Professor Oddone (Italy) being elected President. There were many scientific presentations, but much discussion was also given to the perilous financial state of ISS—a situation that was to continue for many years. The next Assembly took place in Edinburgh in 1936, at which Captain Heck of the USCGS was elected President, the first from outside Europe.

Throughout this time the ISS had continued to produce its bulletin of global earthquake locations, with ever-increasing scientific standards. In 1934 the first travel-time tables of Harold Jeffreys were used in the analysis of earthquakes of 1930. In 1946 the ISS came under the control of the UK Meteorological Office and moved to Kew, and from 1948 the full Jeffreys–Bullen tables were used in the analysis.

At the beginning of the Second World War history was to repeat itself. An Assembly had been arranged for Washington DC, to start on 4 September 1939, and the Secretary-General,

Professor Rothé, had arrived a few days beforehand. As in 1914, hostilities began in Europe in the few days before the planned opening of the Assembly. Professor Rothé was called back to France, but the meeting continued, although with greatly reduced attendance.

Throughout the war, Strasbourg, on the border between France and Germany, suffered greatly from the hostilities, and the University moved to Clermont-Ferrand in Central France, although the seismological station remained in operation. Monthly Bulletins of BCIS continued to be produced until June 1944. The war years also saw changes in the officers of the Association. The President, Captain Heck, became ill and resigned, and Professor Whipple, the Vice-President, died, leaving Dr R. Stoneley (UK) as Acting President. Professor E. Rothé died in 1942, with his work being continued by his son, J.-P. Rothé. After the war it fell to Dr Stoneley and the younger Professor Rothé to reorganize the Association.

Dr Stoneley and Professor Rothé were confirmed as President and Secretary-General respectively at the first post-war Assembly in Oslo in 1948. At the next Assembly, in Brussels in 1951, the Association acknowledged the expanding area of its interest and was renamed the International Association of Seismology and Physics of the Earth's Interior. Thus IASPEI was established in its present form.

2.6 International Association of Seismology and Physics of the Earth's Interior 1951–

Since 1951 IASPEI has continued to expand its work and interests. A pattern has emerged for IASPEI to hold Assemblies every four years, alternately with its parent body, the International Union of Geodesy and Geophysics, and either on its own or jointly with some other IUGG Association. Under a succession of Presidents, Professor J.-P. Rothé remained Secretary-General until 1971, completing a remarkable period during which he and his father had held the post since 1922, almost 50 years. The new Secretary-General was Professor J.-C. De Bremaecker (USA), who although originally from Europe became the first Secretary-General to be based outside Europe. The post returned to Europe in 1979, with the appointment of Dr R.D. Adams, originally from New Zealand but then based at the International Seismological Centre in England. At this time Professor B.A. Bolt (USA) became President and undertook a major restructuring of the IASPEI Commissions to deal with the changing interests of the Association. From this time there also began a fruitful collaboration with UNESCO, involving cosponsoring of many sessions and meetings of mutual interest, particularly in the fields of hazard reduction and training. In 2002 the President is Professor B.L.N. Kennett (Australia) and the Secretary-General Dr E.R. Engdahl (USA). Full lists of Presidents and Secretaries-General are given in an Appendix.

3. International Earthquake Location

3.1 Early International Location

While changes were taking place within the Association, there were also changes in the organization of international earthquake location. In addition to the internationally controlled ISS and the European-based BCIS, many national agencies were undertaking this work. Foremost among them were agencies of the US Government. The first was the US Coast and Geodetic Survey, which from 1928 undertook collection of global earthquake readings and their analysis. This "Preliminary Determination of Epicenters" (PDE) service became one of the accepted standards of excellence and completeness for many decades. Global earthquake location was also undertaken by other national agencies, particularly the Institute of Earth Physics at Moscow.

New interest developed in reliable earthquake location in the aftermath of the Second World War, especially in the need to detect and identify nuclear explosions. Seismologists were early to realize the scientific benefits of being able to use such explosions as known sources of energy to improve their knowledge of travel times of seismic waves, but the nuclear arms race had an even greater effect in that it prompted governments to invest more in seismological recording networks. Foremost among these was the World Wide Standard Seismograph Network (WWSSN) set up by the US Government in the early 1960s. At its peak it comprised more than 100 identical stations placed widely around the globe, each of three-component short-period and long-period instruments. Readings from these stations were used by the PDE service, and made freely available to those interested, as were copies of seismograms.

Interest still remained, however, in an internationally controlled service. The ISS, now at Kew, was continuing to experience financial difficulties and was falling farther behind in its analysis. There was a new development in 1961, when Professor Bolt successfully demonstrated his new computer location program to find a location for the deep Spanish earthquake of 1954. This program was used by ISS for its analysis of earthquakes from 1954.

In its later stages the ISS had a succession of eminent Directors, such as Sir Harold Jeffreys and Dr R. Stoneley, who acted mainly in an advisory and supervisory role, while the day-to-day analysis was undertaken by a small dedicated permanent staff. Particular contributions were made by Miss E.F. Bellamy, and Mr J.S. Hughes, who worked as computer and analyst at ISS from 1923 until his death in 1965.

3.2 International Seismological Centre

Early in the 1960s UNESCO became interested in helping with the problem of international earthquake location, and called an international meeting to consider the setting up of a body to

collect and store worldwide seismological information and produce definitive bulletins of relocated earthquakes. Thus the International Seismological Centre (ISC) was established to come into operation in 1964, taking over the tasks of the ISS. At this stage the funding was still uncertain, with money coming from IASPEI, some national agencies and UNESCO itself.

The founding Director of ISC, Dr P.L. Willmore, insisted that its operation be entirely computer oriented, and requested that all data be submitted in computer-readable form, and that the analysis be undertaken entirely by computer. It was agreed that ISC wait two years before carrying out its analysis in order to make its data files as complete as possible. After some initial difficulties, the Bulletins of ISC appeared monthly, and have remained the definitive global earthquake listings ever since. As with any new procedure, the early program produced some errors in analysis, mainly by associating readings from earthquakes in different parts of the world into a single fictitious event, and by interpreting later phases as first arrivals. With increasing experience, staff at ISC have learned to recognize these, and to override the program's association where necessary.

The new funding arrangements were not working well, so UNESCO called a further meeting of national representatives in 1969. Delegates at this meeting were not keen to set up an official intergovernmental body, but rather opted for an independent Non-Governmental Organization to be established under Scottish law at Edinburgh. These new ISC statutes allowed for a Governing Council of representatives from national seismological agencies that subscribed a minimum subvention. The first meeting of the Governing Council was held at the Royal Society, London, in November 1970, with representatives present from subscribing organizations in six countries, viz. Canada, New Zealand, Soviet Union, Sweden, the United Kingdom and the United States. In addition there was a representative from UNESCO and observers from several other countries that later became members. The Governing Council has met regularly at least every two years, and has now grown to include representatives from more than 50 countries. In 1970 Dr Willmore was replaced as Director by Dr E.P. Arnold from the US Geological Survey. Dr Arnold carried out substantial revision of the Centre's procedures and analysis programs, which with only minor changes remained in use until the late 1990s. In 1975 the Centre moved from Edinburgh to Newbury in southern England to be closer to the large computer at the Rutherford Laboratory, which it was using at that time; in 1986 a further move of a few miles took it to its present location in its own premises at Thatcham.

Dr Arnold returned to the USGS in 1975, as the Centre moved to Newbury, and his place was taken by Mr A.A. Hughes, son of Mr J.S. Hughes. Mr Hughes retired in 1998. It is a tribute to the work of Dr Arnold and others that the analysis systems and programs that they set up in the early 1970s have remained in operation for more than 25 years. Throughout this time, however, there has been a continual honing of techniques,

particularly in analyst assistance to the program in poorly-recorded events, and in deciding the reality of poor associations of stations into events. As well as revising earthquakes already located by other agencies, ISC seeks new, previously unlocated, events, and includes these in its listings after careful examination. During this period the Centre had the benefit of the practical experience of Dr R.D. Adams, who came to the Centre in 1978 from the New Zealand Seismological Observatory, and remained until his retirement in 1995.

Although ISC has continued in its present type of analysis for nearly 30 years, the time has now come for a major restructuring of its procedures, making use of more modern computer systems. This task will fall on Mr Hughes's successor, Dr R.J. Willemann, who brings with him experience from the prototype International Data Centre near Washington, DC, which determines earthquake locations for the intergovernmental organizations involved in the monitoring of nuclear test ban treaties.

4. Present Situation

4.1 Non-Governmental Organizations—ICSU

Figure 2 shows diagrammatically the relationship among various international organizations involved in seismology. On one side we have Non-Governmental Organizations (NGOs), of which the principal is the International Council of Scientific Unions (ICSU). The "ICSU Family" comprises more than twenty Unions covering a wide range of sciences, including IUGG, and hence its constituent Associations, such as IASPEI. Closely related unions include the International Union of Geological Sciences (IUGS), with which IUGG has a joint venture in the Inter-Union Commission on the Lithosphere (ICL). ICSU has other interunion committees, such as the Scientific Committee for Antarctic Research (SCAR) and the Scientific Committee for Oceanographic Research (SCOR). Note, however that the early International Association of Seismology, before the First World War, was in fact an intergovernmental body.

ICSU bodies are generally controlled by national representatives who are elected by their peers in their respective countries, and are meant to be free to act independently, without government influence. Among other NGOs outside the ICSU family are the International Seismological Centre and some engineering bodies such as the International Association for Earthquake Engineering (IAEE), which cooperate closely with ICSU bodies in their relevant disciplines.

4.2 Major International Projects

A major boost to international cooperation came in 1957–1958 with the International Geophysical Year (IGY). This project, run by a special committee of ICSU with the main initiative

FIGURE 2 The organization of international scientific bodies, with those directly involved in seismology shown shaded. Firm administrative links are shown by full lines; broken lines show advisory and scientific links.

from IUGG, embraced not only seismology but many other aspects of geophysics, such as geomagnetism, ionosphere and upper atmosphere studies. International Data Centres were also set up to ensure the free availability and exchange of information. Particular emphasis was placed on improving global coverage of monitoring, and it is from this time that extensive geophysical recording was established in the Antarctic, with many nations setting up bases there, some of which still operate.

The work started in IGY continued afterwards, and the then President of IUGG, Professor V.V. Belousov of the Soviet Union, suggested an International Upper Mantle Project, which ran from 1962 to 1970. It was organized at the initiative of IUGG, but with the active support and participation of the International Union of Geological Sciences (IUGS) and other appropriate Unions of ICSU. The Upper Mantle Project was followed from 1970 to 1980 by the International Geodynamics Programme. It is these activities which have led to the setting up of the present Inter-Union Commission on the Lithosphere (ICL), now jointly run by IUGG and IUGS.

4.3 Intergovernmental Organizations

Foremost among the intergovernmental organizations with an interest in seismology is the United Nations Educational,

Scientific and Cultural Organization (UNESCO) whose Division of Earth Sciences has always played a major part in fostering seismological work, particularly under its early Director, Dr E.M. Fournier d'Albe. Since the early 1980s UNESCO has had a particularly close association with ISC and with IASPEI. Among many joint ventures have been cosponsored sessions at Assemblies, special workshops and training courses. One particularly successful venture was a joint IASPEI/UNESCO/ICL training course in seismology held in Zambia in 1988. UNESCO has also given special support for IASPEI Regional Assemblies, held in India in 1985, Kenya in 1990, Brazil in 1994 and China in 1996. UNESCO's role is to advise, provide expertise and encourage activities. The provision of full-scale programs for equipment and instrumentation is the responsibility of other UN agencies such as United Nations Development Programme (UNDP). The UN Department of Humanitarian Affairs (formerly UN Disaster Relief Organization (UNDRO)) is also active in earthquake hazard mitigation and relief work.

The World Meteorological Organization (WMO) is a UN agency with an operational branch, which has also been involved in seismological matters, particularly data transmission, hazard reduction and technology exchange. This involvement is not surprising, as over a large part of the world, particularly in Africa and Asia, seismology and

seismological recording are undertaken by national meteorological agencies.

There is much mutual benefit from the cooperation between UN agencies and ICSU bodies. Organizations such as UNESCO rely on scientific advice from the scientific unions and associations to help plan their programmes, and at the same time can often provide funding to assist the scientists in their work.

4.4 Committee on Disarmament

The United Nations, through its Committee on Disarmament (CD), has devoted much attention to the setting up of treaties to limit and control the use of nuclear explosions for military and civil engineering purposes. Seismology plays a crucial role in the detection and identification of such explosions and the CD therefore set up in Geneva in the late 1970s an Ad Hoc Group of Scientific Experts to devise means of monitoring any treaty. This Group carried out a series of projects and experiments leading to the establishment of a global network of digitally-recording seismographs with their recordings continuously available for analysis. An experimental International Data Center was set up near Washington DC by the US Government to produce bulletins of global earthquakes since the beginning of 1995. Preliminary solutions are available within a few hours, and the final Revised Event Bulletins (REB) within a day or so, with the readings on which they are based. The results of the IDC, although primarily intended to help in treaty monitoring, are freely available to all participating governments.

Figure 3 shows the distribution of seismic recording stations of this network, which has developed from the ideas first implemented by Milne nearly one hundred years earlier.

The success of the work of IDC has led to the establishment in Vienna of a full-scale organization to monitor by seismological and other means the Comprehensive Test Ban Treaty when it comes into force. The first phase, known as the Preparatory Commission (PrepCom), is now in place.

FIGURE 3 Seismological recording network used in 1999 by the International Data Center to monitor the Comprehensive Test Ban Treaty, including both primary and auxiliary stations.

4.5 Responsibilities of International Location Agencies

There are thus now three levels of international earthquake location, carried out by three different agencies with differing aims. The IDC produces a speedy location, based on a few widely distributed sensitive stations, so that any event of special interest may be quickly identified and investigated further. For this purpose its locations need not be particularly accurate. Next the NEIC of USGS produces its series of publications ranging from the Preliminary Determination of Epicenters files, available in a few days, to their Monthly Bulletins, which appear after about six months. These listings include many more small, regional, events and a fuller listing of station readings than is available to IDC. Finally the ISC produces its publications after about two years, employing and listing all available information for the definitive location of events for tectonic and hazard studies, and station phase readings for studies of earth structure. The three agencies involved fulfil complementary functions, each meeting the needs of a different section of the international seismological community.

4.6 Broadband Seismological Recording

The international location agencies have tended to rely on readings from short-period instruments to give accurate arrival times for the main seismological phases. In recent years, however, seismological recording has moved toward broadband digital instruments, which provide much additional information that can be used for research purposes, as well as for location. To coordinate the setting up and operation of such instruments, in 1986 there was established a Federation of Digital Broadband Seismograph Networks, under the joint auspices of IASPEI and ICL.

Most new stations are now broadband, but apart from the network of the Committee on Disarmament, there is no global network under international control. Many countries, however, operate networks of regional or global extent, usually for research purposes rather than for providing readings mainly for earthquake location. Prominent among these are the French GEOSCOPE network, and the Italian MedNet. A consortium of US institutions, Incorporated Research Institutions for Seismology (IRIS) operates an extensive global network and data exchange facility. Data from broadband recording in Europe are coordinated by ORFEUS (Observatories and Research Facilities for European Seismology) based in The Netherlands.

4.7 International Decade for Natural Disaster Reduction

Following a suggestion by Professor F. Press, an eminent seismologist and then President of the US National Academy of Sciences, the United Nations designated the 1990s an International Decade for Natural Disaster Reduction (IDNDR),

encouraging national, regional and international programmes to alleviate the effects of natural disasters in fields such as earthquake, volcanic eruption, wind storm, flood, landslide, drought, wild fire and insect infestation. This programme produced much focused work relating to seismic hazard assessment, earthquake engineering measures, disaster preparation and management.

5. Regional Cooperation

In addition to the global international activities discussed above, seismology is widely carried out at a regional level. The European Seismological Commission (ESC) is one of the oldest and most active of the IASPEI commissions, with its own statutes and holding regular assemblies. Since 1996 there has also been an Asian Seismological Commission (ASC), with interest in a wide area from the Middle East to the Southwest Pacific. Following the Regional Seismological Assembly in Kenya there was set up an International Commission for Earth Sciences in Africa (ICESA), which also has seismological interests.

Seismological recording in Europe continues to be coordinated by the European-Mediterranean Seismological Centre (EMSC), or Centre Sismologique Euro-Méditerranéen (CSEM), that continued in Strasbourg after the main responsibility for global earthquake location was taken over by ISC. It is now located at the Laboratoire de Détection et Géophysique (LDG) in Paris.

A particularly successful example of regional seismological cooperation is the East African Regional Seismological Working Group. Rather than just discuss policy, the members of this group actively work together. Originally funded by Scandinavian aid agencies, it meets regularly to undertake joint analysis of seismograms from the nine participating countries, which extend from Eritrea and Ethiopia in the north to South Africa. The Group thus produces a combined bulletin of events for the entire region, of a quality much higher than any of the participating countries could produce on their own.

There are many other examples of regional cooperation. The Centro Regional de Sismología para América del Sur (CERESIS) has coordinated South American seismological activities from its offices in Lima for many decades. Similarly, there have been seismological and earthquake engineering organizations for South East Asia with headquarters in Indonesia and the Philippines, and seismological cooperation in the Arab countries has benefited through the Arab Geological Union. These are but a few examples of the regional cooperation that exists around the world.

6. Conclusions

It may be seen that seismology has always been a science that can only prosper if there is full cooperation among

agencies at national, regional and global levels. The above discussion traces the development of the main international agencies for seismological organization and earthquake location, and gives some examples of the many projects that have taken place in the past and some of those that operate today. Seismology is also a science that is continually changing to meet new needs, so in a few years the picture may be somewhat different. The spirit of cooperation that has endured in the past is sure to continue.

Synthesis of Earthquake Science Information and Its Public Transfer: A History of the Southern California Earthquake Center

Keiiti Aki

University of Southern California, and Observatoire Volcanologique du Piton de la Fournaise, La Réunion, France

Where do we come from?
What are we?
Where are we going?

Paul Gauguin

1. Introduction

“A natural disaster will hit us at around the time when we forget about the last one” are household words in Japan coined by Torahiko Terada, a physicist, essayist, and leading intellectual of the early 20th-century Japan, who was also one of the founders of the Earthquake Research Institute, Tokyo University. This statement was an effective warning to the public as well as to officials in charge of public safety through the early part of the 20th century, although it did not contain a bit of scientific information about the phenomena causing the disaster. It was effective because everyone agreed with the statement.

On the other hand, a public warning made on a scientific basis that is still controversial may be ineffective and can bring personal disaster to individual scientists involved. An example is the well known story of Omori and Imamura (e.g., Aki, 1980). Imamura believed in a kind of gap theory (Fedotov, 1965) and anticipated a major earthquake in Sagami Bay near Tokyo, which belongs to a belt of major earthquakes, but lacked historical records. He wrote an article in 1906 warning of the lack of fire-preventing facilities in Tokyo and estimating the death of 100 000 by fire when the Sagami Bay earthquake hit the city. This article was criticized severely by Omori as causing social unrest without solid scientific ground. Imamura had a miserable life for 17 y after the publication of the article until the disaster he predicted actually happened in 1923, causing the loss of 140 000 lives. At the time of this

great Tokyo earthquake, Omori was attending the second Pan-Pacific Science Congress in Australia. During his return trip by sea, his health declined sharply and he died shortly after arrival in Japan.

The lesson we learn from wise Terada, courageous Imamura, and cautious Omori is that we must build a consensus among scientists for an effective transfer of the earthquake science information to the public, and the consensus must represent the true current status of the scientific community that will not suppress an Imamura's view. Terada's warning had no scientific information, which may have correctly represented the status of the scientific community of his time. Imamura had a specific warning based on his concrete idea about earthquakes, which was rejected by a more prominent scientist of his time. A more sensible message from the scientific community at that time might have been to present Imamura's warning with a likelihood of, say, 50% to the public, because it is supported by one scientist, and opposed by another. This may sound meaningless from the scientific viewpoint, but if the public could have accepted such a warning, with a certain degree of response, the disaster of 1923 might have been reduced significantly. It is not easy to implement such a scheme of information transfer when the science is at a rudimentary stage of development and a small number of scientists are involved in earthquake problems of a given region.

Earthquake science has made a great stride in the last three decades with the plate tectonic revolution, wide acceptance of the fault model, and advances in computer technology. The increasing societal need for mitigating earthquake hazard has also been an important factor for its development. Time has come to find an effective framework through which we integrate all scientific information relevant to earthquakes in a region as a consensus of the scientific community, and present

it to the public in the region. The Southern California Earthquake Center (SCEC) was founded for this purpose in 1991, as one of the centers of the US National Science Foundation (NSF) Science and Technology Center program.

The first word “synthesis” in the title of this chapter has a more intense meaning than used normally. A traditional way of synthesizing scientific results was, for example, a joint publication of contributions by various authors, like the present Handbook. There is very little interaction among the authors in this form of synthesis. A traditional way of achieving strong interaction among experts on a complex issue has been to form a working group with a task of producing a consensus report. An example is the Working Group on California Earthquake Probabilities organized by the US Geological Survey (USGS). These working groups have limited lifetimes and disappear after completion of the report. SCEC may be considered as a permanent working group addressing the problem of earthquake hazard in Southern California, participated in by scientists of various disciplines who will constantly interact among themselves for consensus building through workshops, seminars, and report writing.

In the present chapter, I shall describe the concept of a “master model,” which is proposed as a framework for unifying multidisciplinary observations pertinent to earthquakes in Southern California. A first-generation master model was born in the process of creating a public policy document in response to the public need for knowing the probability of major earthquakes in Southern California after the Landers earthquake of 1992. For a healthy growth of a science, the joy and excitement of doing creative science are as essential as effective public transfer of its product. I shall describe how the concept of a master model served the dual purpose at the SCEC.

2. Master Model Concept as a Framework for Unifying Multidisciplinary Observations on Earthquakes

In May 1989, a workshop was held at Lake Arrowhead, California attended by those who were concerned with seismic hazard in Southern California, and they decided to create SCEC and seek its funding from the Science and Technology Center program of NSF. The University of Southern California (USC) was selected as the host institution for the NSF proposal, and I agreed to serve as the Principal Investigator for the proposal on the condition that T. Henyey would help me in administration and management. During the workshop, a subgroup addressing scientific issues came up with the idea of a “master model,” which appears to allow an orderly inclusion of all the research projects proposed by individual participants as its elements.

A consensus was quickly developed to put the master model concept as a central idea of the proposal to be submitted to NSF. As such, the master model was a very vague concept when it was born.

One of my long-term dreams has been to develop a model of the Earth’s lithosphere in which we predict the occurrence of earthquakes on the basis of the space–time distribution of tectonic stress calculated using various geophysical observables, as the atmospheric scientists forecast weather by computer on the basis of observed pressure, temperature, wind speed, etc. Such a model would have an image of physical concreteness and determinism, and could be described in a straightforward manner in a proposal to NSF. Unfortunately, a proposal along this line was obviously too ambitious and premature, because we do not really know enough about the parameters of material properties and constitutive laws as well as boundary and initial conditions needed to define the problem and it was hopeless to produce anything useful for the public during the lifetime of the center (at most 11 y with three cycles of the evaluation–renewal process) along this line. We called the master model along this line a “physical master model,” and I discuss its development at the SCEC later in this chapter.

One thing clear to me at that time was that the master model must be able to absorb all observations pertinent to earthquakes in Southern California. In other words, it must be characterized by parameters that may be effectively constrained by multidisciplinary data including geologic, geodetic, seismological, and historical data on earthquakes in Southern California. After several workshops for preparing the proposal, we recognized the importance of clearly defining the end product expected from the master model. We decided that the end product would be the space–time-dependent probabilities of earthquakes in Southern California and associated ground motions. The master model was defined as a framework through which we should produce this end product by integrating all available information from earth sciences. This scheme is similar to the engineering practice called Probabilistic Seismic Hazard Analysis (PSHA) originated by Cornell (1968) in the western world, but an important difference is that whereas PSHA receives earth science information as given by experts, we generate earth science information by ourselves, and the outcome of PSHA is used to define critical scientific issues to be investigated at the center. Thus, center activities follow a usual scientific cycle of observation, model development, testing the model by comparing predicted with observed seismic hazard, and designing new observations to improve the model. We refer to this model as “hazard master model.”

It was easy for me to accept PSHA as a key element of the master model, because I served as the chairman of a panel that evaluated the usefulness of PSHA upon the request of the US National Research Council. Panel members were divided between earth scientists and hazard analysts, and we had to

overcome a major disagreement before reaching a consensus report.

The disagreement was concerned with assigning likelihood or probability to the validity of a scientific hypothesis, by procedures that are used by hazard analysts to arrive at a decision needed today, when the data are not sufficient for a unique solution. It was not so difficult for me to accept this because I accepted earlier, in my own seismological studies, the stochastic inverse solution in which a model is considered as a stochastic process. In the end all earth scientist members accepted it as a necessary evil.

In the introduction of this chapter, I suggested that giving 50% probability to the validity of Imamura's prediction might have been more sensible than rejecting it. Here is the essence of the hazard master model. If we know the Earth and earthquakes well enough to construct a physical master model, we do not need the hazard master model. At present we do not have enough facts, though we have competing ideas and hypotheses that will be tested against observations in the long run; but the public needs advice today. The master model approach intends to advance science by model testing with observations and to transfer deliverable information to the public at the same time. We all want to indulge in the joy and excitement of creative science, but it is necessary to deliver our product to the public for continued support of science.

Facing societal problems that require multidisciplinary approaches to their solution, we tend to fault the narrowness of a single scientific discipline. But this very narrowness enabled us to dig deeply into a simplified and isolated problem, leading often to a breakthrough. For example, a PhD thesis that tries to cover a broad area is usually less satisfactory than one that gives a definitive solution to a small problem. We recognized the importance of disciplinary independence in the operation of SCEC in order to keep science alive, and created permanent working groups according to disciplines.

The following eight Working Groups were set up as a balanced representation of the research areas of those interested in participating in the activities of the center:

- Group A: Master model and seismic hazard analysis
- Group B: Strong ground motion
- Group C: Earthquake geology
- Group D: Subsurface imaging
- Group E: Crustal deformation
- Group F: Seismicity and source parameters
- Group G: Earthquake physics
- Group H: Engineering applications

Although participation in the center activities was open to anyone interested in earthquakes in Southern California, most of the active participants were from universities, government agencies, and private consulting companies in Southern California, for the reason of obvious ease in attending workshops and seminars. This regional limitation of participants was not a problem for Southern California, because we found

some of the best scientists in the country in each of the above working groups. This is a direct or indirect inheritance of the long history of excellent earthquake science at the California Institute of Technology (Caltech) Seismological Laboratory, which has been a world center of seismology not only in its disciplinary sense (defined, for example, by Aki and Richards (1980) as a science based on records of seismographs), but also in a broader sense of the physics and geology of earthquakes.

The tasks to be carried out by these working groups for constructing the hazard master model were clear for most groups. Groups C, E, and F would contribute to the characterization of earthquake sources in Southern California, and Groups B, D, and H would contribute in calculating ground motion expected from these sources. Group A would integrate these results into products useful for the public. On the other hand, the role of Group G, earthquake physics, was intended to explore, under the protective umbrella of SCEC, paths toward the physical master model, our ultimate goal.

The proposal to NSF was successful, and SCEC began its activities at the beginning of 1991. It quickly established three data centers, the Seismic Data Center (Caltech, USGS) for waveform data and earthquake parameters; the GPS Data Center [University of California at Los Angeles (UCLA), University of California at San Diego (UCSD), and Massachusetts Institute of Technology (MIT)] for GPS survey data; and the Strong Motion Data Center [University of California at Santa Barbara (UCSB)] for strong motion data.

The funding was nearly equally divided between the infrastructure support and research funding. The infrastructure included the operation of the above three centers, visitors program, expenses for meetings, education and outreach programs required for the NSF centers, and the management of the center.

Research funds were, and still are, distributed in the following manner. The process starts with an Annual Meeting of SCEC, where the tasks to be carried out in the coming year are discussed and decided. Each Working Group then discusses its contribution to the decided tasks, and gives priorities to research areas to be investigated in the coming year. Conclusions from the annual meeting are summarized in the form of RFP (request for proposal) and sent to all SCEC members. Short proposals submitted in response to the RFP are reviewed by leaders of the Working Group for the quality of science, and by the Science Director for the contribution to the SCEC tasks. The funding decision is made by a committee composed of the leaders of the Working Group and the board members who represent the core institutions of SCEC [USC, Caltech, UCLA, UCSB, UCSD, University of California at Santa Cruz (UCSC), Columbia University, and USGS until 1998, and now including California State University at San Diego and University of Nevada at Reno].

The above funding decision process implies a matrix approach made of horizontal lines of tasks and vertical columns of disciplines. The task at the highest level may be the

response to a request from the broadest public, and those at lower levels may be in response to more restricted professional and technical user groups. Interactions among different disciplines occur at all levels of tasks, but the more creative, and cutting-edge interactions occur at lower levels, while the consensus-building for public documents is done at higher levels. One may compare the former interaction to the fermentation process and the latter to the distillation, as both processes are needed to produce a fine liquor. The uniqueness of SCEC is this very combination of producing cutting-edge research and passing it along in a timely manner to users.

The Landers earthquake of 1992, the largest earthquake in Southern California since the Kern County earthquake of 1952, occurred in the second year of SCEC, when it had established its working style. Perhaps for the first time in the history of earthquake science, we were ready for a major earthquake, and it occurred just in time. In the next section, I describe how the earthquake helped to pull scientists together to create the first-generation master model for earthquakes in Southern California.

3. The First-Generation Master Model of Earthquake Sources in Southern California

On the morning of 28 June 1992, Southern California was awakened by a very large ($M = 7.3$) earthquake which occurred near the town of Landers, located 30 km north of the San Andreas fault. It was followed by another large one ($M = 6.5$) a few hours later occurring in the Big Bear area 40 km to the west of Landers. People were concerned what this series of earthquakes meant with regard to future earthquakes in Southern California, particularly to the one anticipated on the San Andreas fault, nicknamed the Big One. I felt the need for a quick response to the concerns of the public, and organized a one-day workshop at USC, two weeks after the earthquake, to discuss the implications of these events and SCEC's response. It was attended by SCEC members and key people from the US Geological Survey and the California Department of Conservation's Division of Mines and Geology. It concluded with a decision to produce two reports, Phase 1 and Phase 2. The Phase 1 report would address the short term effects of the Landers–Big Bear sequence on nearby active faults—principally the San Andreas, and the level of ground shaking from potential earthquake scenarios involving the San Andreas fault. The Phase 2 report would extend the study area to the whole of Southern California, and consider the seismic hazard for a longer term. In both reports, the starting point would be the conclusions given earlier in a report entitled “Probabilities of Large Earthquakes Occurring in California on the San Andreas Fault” prepared by the Working Group on California Earthquake Probabilities (WGCEP, 1988).

The Phase 1 report was completed quickly in the fall of 1992, but the Phase 2 report took a long time partly because its innovative nature required a lot of explanation to the broader community of earthquake scientists and to the user community. It was finally published in the April 1995 issue of the *Bulletin of the Seismological Society of America* (WGCEP, 1995). The time spent for the completion was, however, not in vain. The ensemble of the model parameters given in the report is now widely accepted as the first-generation master model of earthquakes in Southern California.

The most radical innovation in the report was the use of crustal strain estimated from the GPS data for seismic hazard estimation as proposed by Ward (1994). Southern California was divided into 65 source zones, and the strain accumulating in each zone was translated into seismic moment according to the Kostrov (1974) formula, thus making seismic moment a central parameter of the master model reducible from geologic, geodetic, and seismological data. Since the GPS network in principle can cover the whole of Southern California uniformly, it can give information on earthquake probabilities in the area where geologic information on faults is lacking. The crustal strain estimated from the GPS data showed more diffused pattern than that inferred from geologic data. This comparison stimulated the group of geologists led by D. Schwartz to come up with the consensus parameters of faults in all of the 65 source zones, making the Phase 2 report go beyond the 1988 Working Group report, which was concerned only with the San Andreas and San Jacinto faults. The importance of this extended areal coverage in the report is clearly demonstrated by the Northridge earthquake of 17 January 1994, the most costly (loss of \$20 billion) earthquake in the history of United States, which occurred off the San Andreas fault.

The Northridge earthquake was no surprise from the perspective of the Earthquake source model described in the Phase 2 report. The earthquake occurred in a source zone characterized by relatively high earthquake potential, falling in the top 13% of Southern California in terms of moment rate per unit area. While the specific fault had not been known prior to the event, the location, magnitude, and style of earthquake were consistent with our expressed understanding of the regional geology and tectonics.

In order to integrate geologic, geodetic, and seismological data, it was important to classify the 65 source zones into Types A, B, and C according to the availability of these data. Type A zones contained faults for which paleoseismic data sufficed to estimate conditional probabilities of earthquake occurrence in the manner of the 1988 Working Group. We allowed, however, for failure over multiple segments in the form of a “cascade” model, in which the amount of slip is characteristic of a segment, but all earthquakes that can occur by combining contiguous segments are allowed. Type B zones contained faults for which geologists had documented possible characteristic earthquakes but information was insufficient for the

conditional probability calculation. For Type C zones, we lacked direct evidence of a preferred characteristic earthquake and we set the seismicity rate to the average of the smoothed catalogue seismicity rate (Kagan and Jackson, 1994) and that corresponding to the geodetic moment rate. By the use of the above classification, we were able to combine existing data from seismology, geology, and geodesy in order to arrive at the preferred model for the whole of Southern California.

Once the preferred model was determined, we could predict the frequency distribution of magnitude for the whole of Southern California. We found that the predicted frequency was about a factor of 2 greater than that observed in the past 150 y. This discrepancy can be explained in the following three ways. First, the seismicity in the past 150 y was anomalously low as compared to the long-term average rate expected from geologic and geodetic data. Secondly, some part of geodetic strain accumulating in the brittle part (assumed to be 11 km thick in this report) may be released aseismically. Thirdly, the maximum magnitude assigned to a source zone using geologic data may be underestimated. All these problems are important from the point of a fundamental understanding of earthquake processes, but we now recognize their importance in practical evaluation of seismic hazard in Southern California and focus our future research on these issues.

Thus, our experience with preparing the Phase 2 report demonstrated all the attributes of the master model, which we described as a framework for integrating multidisciplinary data in the preceding section. Furthermore, the Phase 2 report included the estimation of ground motion and its exceedance probabilities, but was incomplete in this regard because we had neglected the effect of local site conditions on ground motion, which will be the subject of discussion in the next section.

4. Delineation of Local Site Effects on Strong Ground Motion

Once a distinguished earthquake engineer complained to me that engineers read what seismologists write, but seismologists never read what engineers write. So, when I was asked by the geotechnical engineering community to write a review paper on local site effects on strong ground motion, I tried to read papers written on the subject by engineers and engineering seismologists in the United States (e.g., Mohraz, 1976; Seed *et al.*, 1976; Trifunac, 1976a,b; Boore *et al.*, 1980; Joyner and Boore, 1980) and Japan (e.g., Hayashi *et al.*, 1971; Kuribayashi *et al.*, 1972; Katayama *et al.*, 1978; Kawashima *et al.*, 1986). I found remarkably consistent results common to both countries. Soil sites show higher amplification than rock sites for periods longer than about 0.2 sec, while the relation is reversed for shorter periods. This frequency dependence of site amplification is reflected in the site dependence of peak ground motions. Peak ground velocity and displacement show higher

amplifications at soil sites than rock sites, while peak ground acceleration is roughly independent of the site classification.

The conclusion of my review (Aki, 1988) was that the above apparent disappearance of site effect at high frequencies is due to the failure of the broad classification (soil vs. rock) of site condition in capturing the essential factor controlling the site effect at high frequencies. A meaningful microzonation is possible for the frequency range, at least, from 1 to 10 Hz, because the geographic variation of site-specific amplification factor varies by a factor of 10, while the standard error of its variation at a given site for different directions of incident waves is less than a factor of 2.

At the time I wrote the above review, there were no systematic studies on the frequency dependence of site effect on weak motions, and it required another review (Aki, 1993) to conclude the difference between weak and strong motion in this respect. The weak motion amplification is higher for soil sites than for rock sites at least up to 12 Hz in California (Su and Aki, 1995), distinctly different from the frequency dependence of strong motion: a clear indication of the pervasiveness of nonlinearity of ground response in earthquake strong motion.

At the time of my review in 1988, I was aware of only one strong motion record demonstrating the unequivocal effect of nonlinearity of soil, namely, the record of the Niigata earthquake of 1964 obtained near a building that failed completely owing to the liquefaction of soil composed of water-saturated sand. There were other cases suggesting nonlinear soil response. For example, strong ground motion observed in Pasadena during the San Fernando earthquake of 1971 by Hudson (1972) did not show any site dependence, while the amplification factor mapped by Gutenberg (1957) using weak motions of small near earthquakes or large distant earthquakes was distinctly higher at soil sites than at rock sites. These examples, however, can be explained by combination of various linear effects, such as frequency-dependent radiation pattern, absorption, impedance, and scattering effects. I agreed, then, with Esteva (1977), who stated that the influence of nonlinearities is often overshadowed by the overall patterns of shock generation and propagation. In other words, the seismological detection of the nonlinear site effect requires a simultaneous understanding of the effects of earthquake source, propagation path and local geologic site conditions.

The Loma Prieta earthquake of 1989 was the first earthquake for which the simultaneous determination of the above three effects was attempted by Chin and Aki (1991), who found that the amplification factor estimated from weak motion overestimates the peak ground acceleration for sites within 50 km from the epicenter. The amount of overestimation appeared to be in the range expected from geotechnical engineering studies. This discovery changed my position with regard to the soil nonlinearity by 180 degrees, and I began to see pervasive nonlinear effects in various seismic observations, as summarized in Aki (1993).

This change in my position was reflected in SCEC's relation with the geotechnical engineering community. The seismological community has been skeptical about the nonlinear effect (which reduces the estimate of ground acceleration) claimed by the geotechnical engineers primarily on the basis of experiments on small soil samples in the laboratory. There has been very little interaction between the two communities because of the diametrically opposed difference on this most fundamental issue on the site effect. Because of my acceptance of nonlinearity, it was easy for SCEC to have a smooth cooperation between the two disciplines from its inception. We also found, especially through many observations made during the Northridge earthquake of 1994, that the site effect is a much more complicated problem than seismologists used to think, and certainly deserves such a cooperative research. For example, a timely and ingenious deployment of dense seismograph networks by a UCLA group (Gao *et al.*, 1996) after the earthquake revealed that the concentration of damage in Santa Monica was not due to site conditions at shallow depths normally concerned by geotechnical engineers, but to a wave focusing effect by a geologic structure at greater depth. The Phase 3 report, currently under preparation under the leadership of N. Abrahamson, is intended to include the consensus on site effects, in addition to the updates of earthquake source characterization given in the Phase 2 report.

5. Toward a Physical Master Model of Earthquakes like that Used for Weather Forecasting by Computer

As mentioned in an earlier section, we wanted to develop at SCEC a physical master model, a model of the Earth's lithosphere in which we could predict the occurrence of earthquakes based on the space-time distribution of tectonic stress calculated using various geophysical observables as the atmospheric scientists forecast weather by computer, based on observed pressure, temperature, wind speed, etc. For practical reasons, however, we took the approach of a hazard master model that unified observations in the end product, namely, PSHA.

Our practical approach based on PSHA tried to include all accomplishments of earthquake science made in the past three decades on the basis of plate tectonics and the fault model of earthquakes. The concept of seismic moment unified the geologic, geodetic, and seismological data under the constraint from plate tectonics (Aki, 1966; Brune, 1968; and Kostrov, 1974). The concept of characteristic earthquake introduced by Schwartz and Coppersmith (1984) from paleoseismological observations played a major role in translating observed fault parameters, such as the slip rate, amount of slip, and style of fault into earthquake probabilities. The

concept of "cascade" was introduced by D. Jackson into the SCEC Phase 2 report to allow a less restrictive characteristic earthquake model.

The closest thing to what I had in mind as a physical master model for Southern California came from the work by Bird and Kong (1994), done outside of SCEC activities. Their model consisted of a brittle upper crust and a ductile lower crust. Their upper crust model includes all faults with annual slip greater than 1 mm. The deformation of the upper crust is governed by frictional rheology containing a pore pressure effect and specified by different coefficients of friction on the fault and off the fault. The deformation of the lower crust follows the dislocation creep law with the temperature dependence parametrized by the activation energy. The subsurface temperature was estimated from the heat flow at the surface. The boundary condition is given by a standard global model of plate motion. The data to fit with the model are long-term fault slip rates measured geologically, trilateration and very-long-baseline radio interferometry data, and stress orientations from focal mechanisms and *in situ* measurements. The coefficient of friction of the upper crust and the activation energy of the lower crust were free parameters, and they concluded that the coefficients of friction for faults is as low as 0.17, and that a lower activation energy improves the model fit. However, they concluded that the disagreement between the observed fault slip rate and the predicted rate by the best fitting model is too large to allow use of the computer model for practical purposes of seismic hazard estimation. Furthermore, the model of Bird and Kong (1994) was intended for studying a long-term (order of 1000y) behavior of the Earth's crust, while SCEC is interested in the behavior on shorter time scales.

Rock friction behavior in the time scale of interest to SCEC has been systematically studied in laboratory experiments by Dieterich (1972, 1979, 1981), with results generalized in the form of a rate- and state-dependent friction law by Ruina (1983). This law includes a characteristic slip distance L for evolution of surface state and slip weakening. In other words, there is a unique length scale associated with a fault governed by this law specified by a given set of parameters. This length scale unique to a given fault must play a fundamental role in creating the characteristic slip that should repeatedly occur according to the characteristic earthquake model. The SCEC Working Group G (Earthquake Physics) addressed this fundamental problem from the start. For example, Rice (1993) analyzed a 3D static problem of a vertical fault governed by the rate- and state-dependent friction law by discretizing equations involved with the cell size h . He found that the simulated slip shows spatiotemporal complexity when h is greater than a critical size h^* , called "nucleation size," that scales with the characteristic slip distance L . When h is less than h^* , the complexity disappears in favor of simple periodically repeated large earthquakes, namely, the characteristic earthquake. This conclusion highlights the importance of

length scale unique to a fault for our goal of constructing a computer model of earthquakes.

Another fundamental contribution from SCEC to the fault-specific length scale is an unequivocal confirmation of the existence of seismic guided waves trapped in the fault zone of the Landers earthquake of 1992 by Li *et al.* (1994), who estimated a fault zone width of about 200 m, with shear velocity of $2.0\text{--}2.2\text{ km sec}^{-1}$ and Q of about 50 by comparing the observed waveform with the synthetic one. This size of the fault width is consistent with the size of breakdown zone (comparable to the nucleation size mentioned above) estimated by Papageorgiou and Aki (1983) from the upper cutoff frequency (source-controlled f_{max}) of strong motion acceleration spectra for several major earthquakes in California.

Interestingly, a similar estimate of the width of the Landers earthquake fault zone was made by an entirely different method. From a detailed study of tension cracks on the surface, Johnson *et al.* (1994) concluded that the Landers fault rupture was not a distinct slip across a fault plane but a belt of localized shearing spread over a width of 50–200 m. They suggested that this might be a common structure of an earthquake fault, which might have been unrecognized previously because the shearing is small and surficial material is usually not as brittle as in the Landers area. We identify this shear zone with the low-velocity, low- Q zone found from the trapped modes because they occur exactly at the same place. Since the trapped modes were observed from aftershocks with focal depths greater than 10 km, we conclude that the shear zone found by Johnson *et al.* (1994) extends to the same depth.

Repeated measurements of fault-zone trapped waves using artificial sources by Li *et al.* (1998) led to the first discovery of fault healing by a controlled field experiment. The travel times for identical shot–receiver pairs decreased by 0.5–1.5% from 1994 to 1996, with the larger changes at stations closer to the fault zone. These observations indicated that the fault strengthened after the main shock, most likely owing to the closure of cracks that were opened by the 1992 earthquake. In the past, indirect evidence such as time-dependent variations in source properties of repeating earthquakes (Marone *et al.*, 1995) showed some consistency to the healing predicted by the rate- and state-dependent friction law. The new discovery from the trapped mode offers direct evidence for a rather broad fault zone associated with the Landers earthquake. The observation of the fault-zone trapped mode will enable direct estimation of the friction law parameters, serving as a link between the laboratory and the field.

Suppose we have a model of Southern California with fault zones delineated in 3D and characterized by a friction law with known parameters; we need to know how this model is loaded. Some researchers assign the loading at the periphery of the model as the displacement given by the global plate motion, and others give it as a drag exerted on the brittle part of the lithosphere by the deformation in its ductile part.

Castle and Gilmore (1992), for example, found that recent major earthquakes in Southern California are located in the zone of steep lateral gradient in uplift, and hypothesized a localized creep below the zone of steep gradient along the detachment surface between the brittle and ductile part of the lithosphere. The GPS network, currently expanding in Southern California, will give improved information on this matter. The abundantly and easily available seismic information on coda waves of local earthquakes may also be useful for estimating the localized creep, because the observed correlation between coda Q and seismicity has been interpreted by a model of creep along the brittle–ductile boundary (Jin and Aki, 1989, 1993), and there is an indication of low coda Q (Ouyang, 1997) along the zones of steep gradient in uplift found by Castle and Gilmore (1992). In this regard, Aki and Ferrazzini (2000) have found a more powerful method of coda analysis than the traditional coda Q measurement for mapping localized heterogeneities from observations at the Piton de la Fournaise volcano on the Reunion island in the Indian Ocean. The new method appears to give better correlation with the creeping zone geodetically assessed by Castle and Gilmore (1992) when applied to Southern California (A. Jin, personal communication), offering a promising way of studying deformation in the brittle–ductile transition zones in an earthquake region.

When we combine Rice's (1993) analysis based on the rate and state-dependent friction law with the fault zone width estimated from field observations for the Landers earthquake by Li *et al.* (1994, 1998), we will be able to generate a large characteristic earthquake, but unable to generate smaller earthquakes, which were abundantly observed as aftershocks and background seismicity of the region. Among what are missing in Rice's analysis, the following three elements stand out: (1) dynamics of rupture that may produce nonuniform slip and stress roughening on the fault plane; (2) preexisting irregular geometry of the fault, such as segmentation and branching; and (3) preexisting inhomogeneity in the frictional properties including pore fluid distribution.

The contribution from earthquakes other than characteristic earthquakes to seismic hazard was important in Southern California as described in the Phase 2 report, and our physical master model must somehow account for them if it ever is to replace the hazard master model. The only way to include the above three elements into our physical model would be via a stochastic approach, because their detailed specification in any deterministic manner would be impossible now. Thus, our strategy for constructing the physical master model will be separated into a deterministic part dealing with characteristic earthquakes, and a stochastic part dealing with non-characteristic earthquakes. For the deterministic part, the tomographic monitoring of fault zones by trapped mode observation and the monitoring of the loading process at the brittle–ductile transition zone by the geodetic and seismic observations will supply basic parameters of the physical

master model to be used in computer simulation. For the stochastic part, we may learn from the approaches taken by atmospheric scientists in dealing with effects of land surface heterogeneity that spans a wide range of scales. Giorgi and Avissar (1997) reviewed recent studies in this subject area, and suggest that these approaches may be applicable to earthquake faults with inhomogeneous frictional strength, surface roughness, porosity, and permeability that vary across a variety of length scales.

6. Transportability of the Master Model Concept to Other Regions of the World

It is true that the SCEC was possible because of the funding from the federal and local governments and other sources available in the United States, and also because of the scientific manpower available in Southern California. The concept of a master model, however, can be useful for any region with any available funding and manpower. An example is early 20th-century Japan as discussed in the introduction. If we had had a master model including Imamura's hypothesis, and had assigned a certain likelihood to his assessment of damage, and if the government official in charge of the disaster mitigation had accepted it as a consensus from the scientific community, the loss of lives in 1923 might have been reduced significantly. At present, there are many earthquake countries where only a few Imamuras exist. They can apply the master model concept by searching for all the theories and models applicable to their region and taking advantage of the knowledge about them accumulated worldwide.

The advantage of the master model concept comes from the fact that model construction may not be as expensive and time-consuming as data gathering. As mentioned earlier, the construction of the first-generation master model for Southern California was possible only after we divided the region into zones A, B, and C according to the availability of data, adopting different ways of using available data for different zones. As the data gathering proceeds, some of the C zones will be upgraded to B zones, and some of the B zones to A zones. Since the public needs advice today, we must accept the existing data and make the best use of it. This, however, should not be used as an excuse for quitting the data gathering, which is essential for the advancement of science. Keeping a proper balance between the data gathering and model construction is an important part of the master model maintenance, as explained earlier using the SCEC example.

The concept of the master model, however, will be most productive in countries with past extensive developments in earthquake studies, such as Japan, where the emphasis has been placed on multidisciplinary data gathering without much

effort in synthesizing the data as a consensus of the research community. The master model concept will help to develop a quantitative model integrating the data from historical and instrumental seismology, geodesy, and geology, in the manner of the SCEC example. The model will not only give consensus and up-to-date policy documents needed by the public, but also help the scientific community to identify the focus of future research, as the SCEC identified the three most important issues for earthquakes in Southern California, namely, (1) the maximum magnitude expected in a region, (2) the fraction of aseismic strain in geodetically determined deformation, and (3) significance of the long-term change in seismic activity of a region. These issues have been discussed in Japan by individual scientists, but never brought out as a consensus focus of future study by the scientific community. Consensus building among scientists using the master model approach will quench the futile controversies that have been going on among scientists in Japan regarding earthquake prediction research. Earthquake prediction research in Japan has traditionally not included the component of strong ground motion prediction and consequently Japan has not developed a well-established bridge between the community of earthquake engineers and that of scientists, despite the effort of those working in the interface. The situation in the United States has been similar to that in Japan, but we saw some improvement at the SCEC as explained earlier.

The ability to reach a true consensus is a strength of a community, and the inability is a weakness. If the scientific community is divided, nonscientists will take the lead in research and may kill science eventually. As explained in the SCEC example, the master model concept will avoid such a disaster, giving the leadership to scientists in doing the best in creative science and, at the same time, giving the best to the public.

7. Conclusion

The SCEC successfully developed a new concept called "master model" for earthquakes in Southern California, which functions as a framework for integrating all multidisciplinary data on earthquakes in Southern California. The first-generation master model was constructed in response to the public's need for information on future earthquakes in Southern California after the Landers earthquake of 1992. It not only gave the public a consensus view of the scientific community on future earthquakes in Southern California, but also stimulated creative science through vigorous interactions among various disciplines involved in earthquake studies. The first-generation master model unifies the multidisciplinary data through its end product, namely, the PSHA (Probabilistic Seismic Hazard Analysis). Our ultimate goal, however, is to unify the data through a physical model of the Earth's lithosphere containing seismogenic faults. The SCEC made some progress toward

this goal of constructing a “physical master model” both theoretically and observationally. The discovery of seismic guided waves trapped in the fault zone of the Landers earthquake of 1992 and the temporal change in their properties associated with possible healing of the fault measured in repeated controlled experiments will offer a field estimation of the parameters of the rate- and state-dependent friction law, which can be used to develop a computer model of earthquake occurrence relevant to the time scale of interest to SCEC. This deterministic approach may be used for simulating the characteristic earthquake, while noncharacteristic earthquakes may require a stochastic approach for simulation. Thus, the master model approach stimulates the cutting edge research for earthquake science. Furthermore, it is highly transportable to developing countries, where the funding and manpower for research are lacking, because a master model can make use of plausible hypotheses that may compensate for the lack of data. It is, however, most effective for countries where extensive data gathering has been done but little has been done in their synthesis for public use and for the sake of science itself.

Acknowledgment

I thank Paul Jennings, Lucy Jones, Carl Kisslinger, Leon Knopoff, and an anonymous reviewer for their advice and comments on the original manuscript, which were valuable in revising the manuscript.

The idea of forming a center for earthquake research in Southern California was first discussed at a dinner table among Jim Dieterich, Lynn Sykes, Rob Wesson, and myself during the US–Japan earthquake prediction conference at Morro Bay, California in the fall of 1988. After my initial call for a meeting to create the center failed, Ralph Archuleta, Bill Stuart, and I composed an appeal for the center, and circulated it at the AGU fall 1988 meeting in San Francisco. Rob Wesson’s persuasion as the chief of the USGS Office of Earthquakes finally succeeded in organizing the Lake Arrowhead workshop in May, 1989 as mentioned in the text. During the Lake Arrowhead workshop, the name “Southern California Earthquake Research Center” was initially proposed, but Brian Tucker insisted that we drop the word “Research” from it. This turned out to be an extremely important decision as it expressed our commitment to everything about earthquakes in Southern California, including outreach and education. For two years before the official inception of SCEC, Leon Knopoff and I organized monthly seminars on earthquake prediction in which future SCEC members participated. This helped a quick development of cooperation among the members after the official start of SCEC in the beginning of 1991.

During the first site visit by NSF/USGS in 1990 a diagram of the master model drawn by Bernard Minster was used in

every presentation. He served as the vice chairman of the SCEC Board and, among other things, made smooth and complete the transition to the new leadership of Tom Henyey (Center Director) and Dave Jackson (Science Director) after my resignation as Science Director in 1996.

In the workshop held two weeks after the Landers earthquake, strong opposition to the Phase 2 report was expressed by some, who felt that the Phase 1 report, a more traditional public document by scientists in response to an earthquake, was enough. Dave Jackson supported the Phase 2 vigorously, and took leadership in consensus building and writing.

Geoff Martin organized several workshops in which we explained the Phase 2 report to potential users. The subsequent wide acceptance of the report is due largely to his effort. The Advisory Council to SCEC went beyond mere advising, and participated in the growth of SCEC. Its insistence on the need for strategic planning led to the task-discipline matrix approach mentioned earlier. The Council was chaired by Barbara Romanowicz in the formative years of SCEC, who was then succeeded by John Rundle. Its members were C.B. Crouse, Jim Davis, Jim Dieterich, Paul Flores, I.M. Idriss, Tom Jordan, Shirley Mattingly, Dennis Mileti, Bill Petak, Kaye Shedlock, Bob Smith, Cheryl Tateishi, and Susan Tubessing.

Bill Petak used to tell me that “SCEC is a miracle,” watching many people gathered at various SCEC meetings, who competed with each other in the past but now cooperate. The miracle occurred thanks to three incredibly timely earthquakes. The Loma Prieta earthquake of 1989 occurred at the time when the original SCEC proposal was being reviewed at NSF. The Landers earthquake of 1992, in the second year of SCEC, pulled the researchers together to develop the first-generation master model, just in time for the first renewal proposal to NSF. Finally, shortly after the Northridge earthquake of 1994, NSF notified us that the funding increase requested in our renewal proposal was approved. The last earthquake also justified our research focus given to the Los Angeles basin rather than the San Andreas fault.

Important decisions at SCEC were made by the Steering Committee, composed of the Board members representing core institutions (Kei Aki, Ralph Archuleta, Rob Clayton, Tom Heaton, Dave Jackson, Karen McNally, Bernard Minster, Jim Mori, Nano Seeber), the Working Group leaders (Duncan Agnew, Kei Aki, Ralph Archuleta, Rob Clayton, Steven Day, Egill Hauksson, Dave Jackson, Leon Knopoff, Geoff Martin, Kerry Sieh), Executive Director (Tom Henyey), Director for Knowledge Transfer (Jill Andrews), Director for Education (Curt Abdouch), and Director for Administration (John McRaney). The last four mentioned above have formed the core of the SCEC operation, implementing the decisions made by the Steering Committee to run a highly complicated organization.

Last but not least, Jim Whitcomb served as the NSF program director for SCEC.

Continental Drift, Sea-Floor Spreading, and Plate/Plume Tectonics

Seiya Uyeda

International Frontier Research Group on Earthquakes, Riken, Japan

1. Introduction

The study of the solid Earth began with land geology at the time of the industrial revolution about 200 years ago. With a wealth of knowledge on orogenic zones like the Alps and Appalachians available early, grand concepts were developed like those of geosynclines. From around 1900 onward, with the aid of physics and new technologies, geophysical research such as geodesy and seismology began to flourish, and the principle of isostasy and views on the Earth's major internal layered structure were established. Despite all this and its long history, however, geodynamics remained a highly speculative subject (Scheidegger, 1963).

The theory of continental drift proposed by Alfred Wegener in 1912 was largely discredited until paleomagnetic research (e.g., Runcorn, 1962) accomplished its dramatic revival after World War II. At almost the same time in the late 1950s, marine geology and geophysics (marine G&G) were established as disciplines and led rapidly to important discoveries on the sea floor. These discoveries in turn led to new ideas, such as the world-encircling oceanic rift system (Ewing and Heezen, 1956) and the sea-floor spreading hypothesis (Dietz, 1961; Hess, 1962; Vine and Matthews, 1963). The late 1960s brought their glorious verification.

A further turning point was the proposal of transform faults by Wilson (1965a) and of plate tectonics. Morgan (1968), McKenzie and Parker (1967), and Le Pichon (1968) worked out the fundamental part of the kinetic theory of plate tectonics. In a narrow sense, plate tectonics postulates that the Earth's surface is divided into ten or so blocks moving in large-scale horizontal motions with little deformation (see figure 8 of Chapter 7 by Stein and Klosko). If plates are moving without deformation, their motion can be described by rotation around a pole, called the Euler pole (see also Chapter 7).

There are three main types of plate boundaries: divergent, convergent, and sliding boundaries, representing spreading ocean ridges, subducting and colliding zones, and transform faults, respectively. There are two kinds of ocean-continent boundaries: the active and the passive margins. An active margin is a (convergent) plate boundary, whereas a passive margin is not a plate boundary. Building on these postulates, plate tectonics in the broader sense provided, for the first time, a unified explanation of major geologic phenomena in terms of plate formation, evolution, and interaction (e.g., Dewey and Bird, 1970). Wilson (1968c) stressed that what was going on in the 1960s was a scientific revolution or paradigm change (Kuhn, 1962).

However, plate tectonics explains only the orogenic phenomena that have occurred in the superficial parts of the Earth during its later history. To understand the long-term changes in orogenic characteristics, an understanding of the mantle dynamics underneath the lithospheric plates was needed. Based mainly on the deep seismic tomography that has indicated the existence of possible upwelling superplumes beneath the South Pacific and Africa and a downwelling superplume beneath central Asia, the so-called plume tectonics has been postulated (e.g., Maruyama, 1994). Now, at the threshold to the 21st century, a changing view of the Earth from plate tectonics towards plume tectonics seems to be well underway. In the following, a brief attempt will be made to reflect how these views of the Earth have been developed. References are not exhaustive but often limited to reviews and textbooks, through which more in-depth information and original references can be traced. Examples are Wyllie (1971), Bird and Isacks (1972), Le Pichon *et al.* (1973), Cox (1973), Uyeda (1978), Bird (1980), Turcotte and Schubert (1982), Cox and Hart (1986), Allegre (1988), Kearey and Vine (1990), Sullivan (1991), and Sleep and Fujita (1997).

2. Continental Drift Theory—Its Birth, Death, and Revival

2.1 Wegener's Theory

Alfred Wegener (1880–1930) was not the first to notice that continental outlines fit together like the pieces of a jigsaw puzzle (Fig. 1), but it was he who made this idea part of modern earth science. His major work, *Die Entstehung der Kontinente und Ozeane* in 1915, went through three revisions before his death (Wegener, 1929). Probably because Wegener was basically a meteorologist, many of his arguments related to the solid Earth are erroneous from the perspective of present-day

knowledge, yet it was his book that broke down the wall between geophysics and geology. It makes fascinating reading even today.

In addition to fitting the “pieces of the puzzle,” Wegener used a variety of arguments to demonstrate a past linkage of continents that are now separated. Indeed, geologists had found supporting evidence of past connection between far-apart continents. This included fossils of animals that could not have crossed vast oceans and clear signs of the Permo-Carboniferous glaciation in different continents. The Austrian geologist, Eduard Suess (1831–1914) had already given the name “Gondwanaland” to the imaginary protocontinent in the Southern Hemisphere. However, geologists simply assumed that continents now separated by oceans had once been connected by land bridges. Wegener refuted this idea, arguing that the principle of isostasy would not allow for the submergence of such vast land bridges.

Furthermore, Wegener held great insight into orogenesis, or the mountain building process, which is one of the most important problems in solid earth science. In his time, the popular view about the folded structure seen in great mountain ranges was to assume that the Earth had contracted as it cooled. Wegener rejected this view because it could not be quantitatively justified. Instead, largely referring to the then pioneering works of Swiss geologist Emile Argand (1879–1940) on large mountain ranges such as the Alps and the Himalayas, he contended that they were created by collisions of continents.

Wegener's theory of continental drift unleashed a heated controversy. It could not, however, overturn the belief in the “fixist” (static) Earth that was prevalent. After Wegener's tragic death during his 1930 Greenland expedition, his theory went into decline and was almost completely forgotten by the 1940s. The main objection had been that the forces that allegedly moved the continents could not be explained. The forces proposed during Wegener's days included tidal forces exerted by the Moon, and the so-called “*Polfluchtkraft* (centrifugal force from the poles).” However, the British theoretical geophysicist Sir Harold Jeffreys (1891–1989) demonstrated that these forces are many orders of magnitude smaller than those required to move continents. Wegener himself lamented that “the Newton of the Continental Drift Theory is yet to arrive.” The mantle convection theory proposed by another British scientist, Arthur Holmes (1890–1965) as early as in 1929 provided the only hope (see, e.g., Holmes and Holmes, 1978), but Holmes was a minority of one.

FIGURE 1 Reconstruction of the map of the world for three periods according to Wegener's theory of continental drift. The dark-shaded areas represent shallow seas.

2.2 Paleomagnetism and the Revival of Continental Drift Theory

The main geomagnetic field can be approximated by a geocentric magnetic dipole and several higher spherical harmonics, representing regional nondipole magnetic fields. They are caused by electric currents within the Earth's fluid outer core

and exhibit secular variations, while local geomagnetic anomalies are caused by the magnetization of crustal rocks. Paleomagnetism attempts to reconstruct the geomagnetic fields of the past by studying the natural remanent magnetism (NRM) of rocks. The NRM can preserve a record of the geomagnetic vector present at the time when the rocks formed (e.g., Nagata, 1961). Paleomagnetic research was pioneered in the 1950s by British and American scientists (e.g., Irving, 1964). Their main accomplishment was the establishment of (1) geomagnetic reversals, (2) geomagnetic polar wandering, and (3) continental drift.

It had been known since the early 20th century that the NRM of some Cenozoic igneous rocks is oriented opposite to the present geomagnetic field. On the basis of these observations, scientists began considering the possibility that the geomagnetic field has occasionally reversed its polarity in the geologic past. To test this hypothesis, Cox and others launched vigorous study of geologically young igneous rocks all over the world. Their results indicated that there were as many as four reversals during the last 5 My (Cox, 1973). Each polarity epoch, named after the pioneers of geomagnetic research, lasted for about 10^6 years. Within a polarity epoch are a few shorter (less than 10^5 years) polarity events each identified by the region where first found. Ever since the Vine–Matthew–Morley hypothesis in 1963 used the geomagnetic reversals to explain the stripe-patterned geomagnetic anomalies of the ocean floors, the concept of geomagnetic reversal has played a major, albeit unexpected, role in the plate tectonic revolution. Today, the history of geomagnetic reversals stretches back almost 190 My (see Section 3).

In a paleomagnetic study, the past position of the geomagnetic pole can be calculated from the direction of NRM with the assumption that the Earth's magnetic field has always been dipolar. The pole position thus obtained is called a "virtual" geomagnetic pole (VGP). The geomagnetic pole after averaging the fluctuation due to secular variations is called a paleomagnetic pole. It is the latter pole that is important in our discussion. The paleomagnetic poles of the Cenozoic Period obtained from all continents are concentrated around the present geographic pole. For older ages, paleomagnetic poles systematically deviate from this position. The locus of the paleomagnetic pole is called the apparent polar wander (APW) path. It is "apparent" because the wander is relative to the continent or plate from where the rocks were sampled. Figure 2a shows the APW paths for the European and North American continents with the assumption that continents did not move. If the geomagnetic field had always been dipolar and if the continents had not drifted, the two APW paths should coincide. But it is obvious in the figure that they are two distinct curves. On turning the North American continent counterclockwise around the North Pole so that the Atlantic Ocean closes, as in Figure 2b, the APW paths overlap for a long period from the Silurian (Paleozoic) through the Triassic (Mesozoic) Period. This agrees with the assumption that Pangea was one continent during that period, and that the drifting apart of the North American and European continents began in the late Triassic–Jurassic Period, or thereabouts, when the two paths began to deviate.

It was mainly Runcorn, Irving, and other British scientists of the 1950s who provided, with these results, the most

FIGURE 2 (a) Comparison of apparent polar wandering (APW) paths for North America (circles) and Europe (squares). (b) The two APW paths after closing the Atlantic Ocean. K, Cretaceous; J, Jurassic; Tr, Triassic; Tru, Upper Triassic; Trl, Lower Triassic; P, Permian; Cu, Upper Carboniferous; S–D, Silurian–Devonian; S–Cl, Silurian–Lower Carboniferous; C, Cambrian.

significant evidence for the continental drift since Wegener's time. Thus by the end of the 1950s the continental drift theory, which had seemed all but dead for decades, was suddenly revived in the geoscience community, especially in the British paleomagnetic community. It was, however, a far from unanimous acceptance even in the United Kingdom. When the present author visited there in 1958, he was constantly asked, "Do you believe in continental drift?" Many of those who posed this question at that time could have been half-doubters. It took some years for the revival of the continental drift to be globally accepted and become the principal topic in earth science. For instance, Hurley (1968) at MIT demonstrated that the age distribution of ancient rocks in South America and Africa coincides with the Pangea reconstruction obtained by the use of the then newly introduced electronic computer at Cambridge University (Bullard *et al.*, 1965).

3. Sea-Floor Spreading Hypothesis and its Verification

3.1 Hess–Dietz Proposal

With unexpected help from paleomagnetism in the late 1950s, the continental drift theory, little by little, gained wide acceptance. As for the driving force for the motion of continents, mantle convection arose as a promising possibility. At about the same time, as mentioned in the Introduction, marine geology and geophysics (marine G&G) became very active and many new discoveries began to emerge. Based on these marine surveys, Ewing and Heezen (1956) at Lamont Geological Observatory introduced the idea of world-encircling rift system (e.g., Heezen, 1960). A breakthrough came when Hess (1962) and Dietz (1961) introduced the insightful hypothesis of sea-floor spreading. Hess focused his attention on the facts about the mid-oceanic ridges then coming to light, such as the high heat flow, the median rift valley, the shallow earthquake activity, and the presence of anomalously low seismic wave velocity in the upper mantle. Hess proposed that when mantle convection rises under a mid-oceanic ridge, it produces new oceanic crust, which then divides and migrates to either side of the ridge (Fig. 3). When mantle convection rises under a continent, the continent will split and drift "passively." New sea floor is produced in the wakes of the continental fragments. Where the leading edge of the moving continent collides with a mantle current, the mantle subducts and an oceanic trench is formed. Since the continents are too buoyant to sink, they are deformed and produce a mountain range when they collide.

For the first time, Hess' theory explained why the thickness of the ocean sediment was one order of magnitude thinner than the estimate obtained by multiplying the age of the sea by the sedimentation rate. It also explained why rock older than Cretaceous had never been discovered on the sea floor. These facts were no longer mysterious; the entire sea floor sinks into

FIGURE 3 Schematic cross-section of the Earth based on the sea-floor spreading hypothesis.

the mantle in a matter of 200–300 My with new sea floor constantly replacing it. Dietz's paper (1961), in which he coined the term "sea-floor spreading" was not as geopoetic, but was even more convincing. He was already proposing, for example, that a hard lithosphere approximately 70 km thick lay over a softer asthenosphere.

As can be guessed from the remark by Hess in the foreword of his paper, "I should consider this paper an essay in geopoetry," the whole idea was quite remote from the common sense in the geoscience community. Those geoscientists with mobilist views welcomed these papers, but the wider majority, for whom even to accept the continental drift theory was sufficiently risky, were skeptical. Researchers of the day would greet one another with, "Do you believe in sea-floor spreading?" Actually, Holmes had suggested a similar idea back in 1929 as mentioned earlier, but little attention was paid to it. As in the case of Wegener's continental drift theory, scientists usually distrust innovative ideas.

3.2 Supporting Evidence

With the appearance of the sea-floor spreading hypothesis, solid earth science of the late 1960s was abuzz with discussion of it. Findings from marine geology and geophysics were generally consistent with the hypothesis, but some reported that their findings were not.

Oceanic ridges and trenches are in contrast with regard to many features. The former sit in the middle of the ocean, while the latter are found on the margins. The seismic activity (see Chapter 7 by Stein and Klosko) directly below oceanic ridge axis is limited to small magnitude ($M < 6$) shallow ($d < 10$ km)

earthquakes, apparently caused by the tensile stress associated with sea-floor spreading. In contrast, earthquakes at trench areas include shallow low-angle thrust types (including the $M > 8$ class great earthquakes) and deep-focus earthquakes, associated with the subduction of the sea floor. The contrast in heat flow (see Chapter 81.4 by Cermak), which is anomalously high over the mid-oceanic ridges, and low in the trench areas, is also supportive of the hypothesis.

By far the most decisive support of sea-floor spreading was provided by the geomagnetic anomalies of the sea floor. The development of electronic devices during the 1950s made it remarkably easy to make continuous and accurate measurements of the total geomagnetic force at sea. Armed with new tools, scientists, mainly from the Scripps Institution of Oceanography of the University of California, led by V. Vacquier, began extensive surface ship geomagnetic surveys over the eastern Pacific, and made a startling discovery. As demonstrated by Raff and Mason (1961), for instance, there are striking zebra-striped patterns of geomagnetic anomalies, with widths of 20–30 km and lengths of several hundred kilometers in the northeastern Pacific off the coast of North America. And that was not all. Here and there across topographic discontinuities called fracture zones, the stripes showed displacements as great as many tens of kilometers. Such strange geomagnetic anomalies have never been seen on land. Vine and Matthews (1963) provided an intriguing answer to the question of the origin of these striped patterns. If the sea floor spreads, the newly produced sea floor would be magnetized parallel to the geomagnetic field of the time. If at the same time the geomagnetic field keeps reversing its polarity, the sea floor would inevitably be magnetized with positive and negative stripes. This model, which can be likened to a magnetic tape recorder, has proven to provide the most powerful time frame for plate tectonics and today leaves little room for doubt. But it was regarded as extreme and too speculative when it was first proposed. To be exact, it would better be called the Vine–Matthews–Morley Hypothesis, including L.W. Morley from Canada, who submitted a paper with almost identical content to scientific journals independently, but was unable to get it published. As this episode tells, the tape recorder model was initially not taken seriously by the general geophysical community.

However, there was a real breakthrough at about 1965 (Vine, 1968). Assuming that the crust is magnetized alternately in stripes, the magnetic field on the ocean surface can be calculated. In early 1965, Pitman obtained a high-quality magnetic profile, the famous Eltanin-19 profile, over the East Pacific Rise south of Easter Island. It was then demonstrated that the pattern of the geomagnetic intensity anomalies on either side of the Rise agreed perfectly with the model based on the geomagnetic reversal history that had been obtained from the paleomagnetic studies of rocks on land (Pitman and Heirtzler, 1966). Vine and Wilson (1965) demonstrated the same for the Juan de Fuca Ridge off Vancouver Island. For instance, Figure 4 shows the remarkable agreement between

calculated and observed geomagnetic field anomaly profiles of the Pacific–Antarctic Ridge. In the meantime, the geomagnetic reversal history was pursued in a different way (e.g., Opdyke, 1972). The history of the geomagnetic field for several million years could be continuously analyzed by looking at the magnetization of some 10 m of core samples from sea floor—since the sedimentation rate on the deep sea floor is extremely slow. Their results also quantitatively agreed with the reversal history based on volcanic rocks on land. Thus, identical results were obtained from three independent sources—volcanic rocks on land, deep-sea sediments, and the marine magnetic anomalies. This “trinity” was irrefutable evidence not only of geomagnetic reversals but also of sea-floor spreading.

By the time the Vine–Matthews–Morley hypothesis was established for the past four or so million years, attempts to extend this hypothesis to older sea floors were already underway by Heirtzler and others of the Lamont-Doherty

FIGURE 4 The magnetic tape recorder model. (a) Geomagnetic reversal history according to Cox (1973). (b) Comparison of computed and observed anomaly profiles for Eltanin-19 according to Vine (1966). (c) The pattern of normal and reverse magnetizations of oceanic crust with a transform fault.

Geological Observatory of Columbia University. Such research was possible only at that institution, thanks to the enormous amount of surface ship geomagnetic data that had been amassed under the leadership of Maurice Ewing. They analyzed the long and numerous geomagnetic profiles for each of the world oceans and, by 1968, had demonstrated that magnetic stripe patterns in different oceans are correlated as far back to some 80 My old sea floor (Heirtzler *et al.*, 1968).

As each stripe represents sea floor produced at the same time, it is called an isochron or chron. Some prominent isochrons were given numbers. The problem they had was that the ages of isochrons were not known for the period older than 4.5 My. Heirtzler and his colleagues, however, extrapolated the age by assuming that the sea-floor spreading rate of the South Atlantic was constant. Their assumption was proved to be correct by the DSDP (Deep Sea Drilling Project) in 1968 (Maxwell and von Herzen, 1969). In this way, a magnetic lineation map consisting of isochrons was translated into a map showing the age of the ocean floor. Thus, by about 1974, the age of almost the entire world's ocean floor was determined (Fig. 5; Pitman *et al.*, 1974).

There are several features to be noted in relation to Figure 5. (1) The oldest sea floor of Jurassic age lies in an area east of the Mariana Arc in the western Pacific. The present Pacific Plate was born there about 190 Ma (Hilde *et al.*, 1977). Of course, this does not mean that the Pacific Ocean at that time was zero in area. On the contrary, the Ocean was much larger but was occupied by other, now subducted, plates. As the present Pacific

Plate grew, the spreading ridge (East Pacific Ridge, EPR) migrated eastward and the sea floor produced in the eastern side of the ridge was continuously subducted under North America. Finally, the ridge itself collided with North America and was subducted. The collision of ridges with trenches, however, was rather puzzling from the view that regards oceanic ridges as upwelling zones and oceanic trenches as downwelling zones of mantle convection. How can an upwelling flow go down? Belousov (1979) used this apparent contradiction to attack the "new view of the Earth." But the observation does require the subduction of spreading ridges, with some important implications. (2) Although not shown in Figure 5, the vast area shown as Cretaceous age is characterized by absence of striped magnetic anomaly lineations. It is therefore called the Magnetic Quiet Zone (MQZ). This vast sea floor is interpreted to have been produced during an abnormally long absence of geomagnetic reversals. Taking into consideration the width of the MQZ and its age span, the rate of sea-floor spreading seems to have been 50–75% faster during the Cretaceous Period (124–83 Ma) than during other periods. Larson and Pitman (1972) called this phenomenon a pulse. When spreading is faster, the area with young age increases. Given the fact that the sea depth increases with age, they proposed that the sea floor must have risen during the pulse period, causing the Cretaceous "transgression of the sea," a long-known fact in geology. This pulse of spreading, with a long period of no geomagnetic reversal, was speculated as related to mantle superplume activity (Larson, 1991). This was the dawn of plume tectonics.

FIGURE 5 Age of sea floor as established by W.C. Pittman and others at Lamont in 1974.

4. Advent of Plate Tectonics

4.1 Transform Faults

As mentioned in Section 3, geomagnetic stripes are displaced many tens of kilometers (sometimes as much as 1400 km) at many places across fracture zones. According to the idea of transform faults (Wilson, 1965a), the offsets do not represent relative motions between crustal blocks. Wilson, visiting Cambridge University at the time, is said to have demonstrated his elegant new idea by using a simple paper cutout. As a typical example, let us consider the case shown in Figure 6b. This kind of fault is often seen on mid-oceanic ridges. If the spreading rate is the same on both sides of ridge, we can see that (1) the relative motion occurs only between the two oceanic ridges ($b-b'$) and not along the fracture zones ($b-f$, $b'-f'$); (2) the direction of the slip (“left-lateral” in this case) between b and b' will be opposite to the direction of the displacement of the ridge, i.e., of the magnetic stripe pattern. In an ordinary transcurrent fault situation, as in Figure 6a, neither of the above would hold. Sykes (1967) convincingly demonstrated, through seismological means, that both (1) and (2) actually occur (see Chapter 7 by Stein and Klosko; Isacks *et al.*, 1968). This new type of fault—the transform fault—cannot be understood without the concepts of sea-floor spreading and rigid tectonic plates. But if one accepts these concepts, transform faults are an inevitable consequence. In active transcurrent faults (Fig. 6a), the displacement $B-B'$ increases with time. In the transform faults (Fig. 6b), on the other hand, the ridge displacement $b-b'$ does not change with time, implying that the offset has been there from the beginning. This may sound somewhat strange, but Wilson argued that the crust may have cracked at the time of the continental split along some “weak zones” that had already existed, and that the form of the cracks was later reflected in the displacement of the oceanic ridge.

Wilson further proposed that the mobile zones, such as oceanic ridges, and orogenic belts, were not isolated features, but that they form a network that divides the Earth’s outermost layer into blocks—the plates. Transform faults play a key role

in this network, by transforming, for example, a segment of a ridge to another kind of plate boundary. This realization was truly the beginning of plate tectonics. Other types of transform faults, such as those connecting an oceanic ridge and a trench, or two oceanic trenches, are also possible. Depending on the type of transform faults, the displacements, i.e., the length of faults, can remain constant as in the case of Figure 6b, or increase or decrease with time.

A remarkable example of transform faults on land is the San Andreas Fault in California. It was long known that among the active zones of the circum-Pacific Belt, the western coast of North America alone lacked oceanic trenches and deep-focus earthquakes. Instead, it had what looked like an enormous transcurrent fault and accompanying “right-lateral” earthquakes. The cause for these anomalous characters of the western coast of North America was totally unknown. The mystery can be neatly explained, however, when we consider a scenario in which East Pacific Rise becomes a transform fault as it enters the Gulf of California from the south (Fig. 7). If this is true, there should be a spreading ridge at the north-western end of the San Andreas Fault. Sure enough, Juan de Fuca and Gorda Ridges were found exactly where expected. With the introduction of the transform fault, the stage for plate tectonics was ready.

4.2 Rigid Body Rotation

Using Euler’s Fixed Point Theorem, one can conveniently express the displacement of a plate by a rotation around its Euler pole (see Chapter 7 by Stein and Klosko). To describe the motion of, say, the North American Plate, one does not have to specify how many kilometers San Francisco moved in which direction, or what happened to New York, etc. Let us write the rotation of Plate A relative to Plate B as ARB , its Euler pole as APB , and relative velocity and relative angular velocity as AVB , and $A\omega B$. When plate tectonics was introduced, its goal was to substantiate the supposed rigid motion of plates. For this purpose, the proof that actual plate motions satisfied Euler’s theorem was sufficient. Consider the case of two plates A and B

FIGURE 6 (a) Ordinary transcurrent fault. (b) Transform fault.

FIGURE 7 The San Andreas Fault as a transform fault. The double lines are the spreading ridges; dots are earthquake epicenters.

(Fig. 8). The plate tectonic theory predicts the following: (1) The direction of the relative motion between A and B, i.e., the direction of the transform fault, *should* be parallel to the small circle on the globe with APB as its pole; (2) the magnitude of the relative velocity *should* be in proportion to $\sin(q)$, where q is the angular distance from APB . A more intuitive picture would be a world map using a Mercator projection, but with the Euler pole APB as its pole. We see that the direction of the relative motion (i.e., the transform fault) is parallel to the lines of “latitude,” and the length of the vector that represents the relative velocity is constant regardless of “latitude.” Confirmation of these predictions was the starting point of plate tectonics.

McKenzie and Parker (1967) investigated the relative motion of the Pacific Plate and the North American Plate, and saw that the projections onto the horizontal plane of slip vectors of several earthquakes at the boundaries of these two plates were nearly parallel to the lines of “latitude” in a Mercator projection with Euler pole at 50°N , 85°W . The Euler pole position was determined from the directions of San Andreas Fault and the average slip vectors of aftershocks of the 1964 great Alaskan earthquake in the Kodiak Island region of the Aleutians.

FIGURE 8 Relative motion of plates A and B, represented by a rotation around the Euler pole.

Morgan (1968) began independently with the same concept, but expanded it to encompass the global view. He took into consideration not only slip vectors of earthquakes and the directions of transform faults, but also the distribution of the spreading rate estimated from the width of geomagnetic stripes. For example, he determined the Euler pole of the relative motion between the American and African Plates (1) from the points of intersection of great circles perpendicular to both transform faults and slip vectors of earthquakes associated with the Mid-Atlantic Ridge and (2) by matching the distribution of spreading rates with the relations of $\sin(q)$. These independent estimates agreed well.

Le Pichon (1968) was inspired by Morgan's work and enthusiastically proceeded to undertake a systematic verification of the plate theory. He divided the Earth's surface into six large plates, and tried to find, by the method of least squares, the set of plate motions that would best fit with both the width of geomagnetic stripes and the strikes of the transform faults. He then drew a Mercator projection with the Euler pole thus obtained as its pole, and demonstrated that the two “*shoulds*” stated above were satisfied.

A natural extension of the plate tectonic methodology is its use for quantitative reconstruction of continents and

ocean basins in the geologic past. Where dated sea-floor spreading magnetic lineation patterns are available on both sides of a ridge, the part of the sea floor between the ridge and an isochron can be resorbed by appropriately rotating the plates and this gives past positions of the plates (continents and ocean basins). Le Pichon (1968) pioneered this type of reconstruction, which has been followed by many, including McKenzie and Sclater (1971) for the Indian Ocean and Pitman and Talwani (1972) for the Atlantic Ocean. Where subduction plays major role, namely, the Pacific Ocean, it is not possible to estimate the past position of continents from magnetic lineations alone, but the evolution of the Pacific Ocean itself and its margin can be discussed (Hilde *et al.*, 1977).

4.3 Triple Junctions

A closed surface cut into more than two plates will inevitably produce a point where three plates meet, called a triple junction. Triple junctions are endowed with many interesting characteristics (McKenzie and Morgan, 1969). For example, some triple junctions maintain their configurations indefinitely, while others can exist for only an instant in time. They are called, respectively, stable and unstable triple junctions. Let us first look at the example seen in the bottom right corner of Figure 7, where three spreading ridges meet. Such a triple junction, called an “R-R-R” type, is stable because it can persist without causing any change in plate configuration. Consider next a “T-T-T” triple junction, consisting of three trenches (Fig. 9a). Take plate A as the reference and consider the motions of plates B and C relative to A. The arrows in this figure represent the relative motion vectors across the trenches. Assume that at a trench, the plates without tooth marks subduct beneath the plates which have tooth marks. After a certain length of time, the leading edges of Plates B and C will reach the positions marked by the broken lines in Figure 9b, causing changes in the configuration of plates around the triple junction: namely J_1 becomes J_2 . This change means that J_1 was an unstable triple junction. But as J_2 continues to move

north along the trench AB, the plate configuration no longer changes. The triple junction has stabilized.

Another interesting point is that an observer at point P, for instance, watching Plate B subducting beneath Plate A (on which he stands), will see, after a few moments in geologic time, that he is now watching Plate C subducting in front of him. Which plate is subducting from which direction is a matter of importance for the tectonics of the region, yet this drastic change—from Plate B to C—can occur while there is no change in the motion of the three plates. As plate boundaries also include transform faults (F), various combinations of R, T, and F can be considered as types of triple junctions. McKenzie and Morgan (1969) made an elegant general treatment of the stability of triple junctions using the velocity space presentation. Their paper also demonstrated that the concept of the triple junction was more than a theoretical game by applying it to explain how the San Andreas Fault came to exist.

4.4 Relative and Absolute Plate Motions

In plate tectonics, clearly definable motion is the relative motion (rotation) between two adjacent plates. The major data sources are the width of magnetic lineations and directions of transform faults and slip vectors of interplate earthquakes. Except for the last item, the data represent the features concerning geologic time scale of millions of years. Therefore, it was not certain how plates are actually moving today in a human time scale. However, recent dramatic developments in the so-called space geodesy, notably the Global Positioning System (GPS), has proven that plates are moving almost exactly as plate tectonics postulates. GPS is actually bringing about a revolutionary progress in earth science. The beauty of GPS is its extreme accuracy for its simplicity and inexpensiveness, as laymen can easily realize through automobile navigation systems.

The plate motion models have been improved over the last decades, the most recent being NUVEL-1A (Fig. 10a; DeMets *et al.*, 1994). If there were points fixed to the main body of the Earth, motion relative to them could be termed absolute motion. As the candidate of such points, hot spots like Hawaii

FIGURE 9 T-T-T type triple junction (after McKenzie and Morgan, 1969). Arrows are velocity vectors of subducting plates relative to the upper plates. (a) At time = 0; (b) after some time.

FIGURE 10 (a) Relative plate motion (prepared by K. Tamaki, based on NUVEL-1A; DeMets *et al.*, 1994). (b) Plate velocities relative to the hotspots by models HS2NUVEL1 (thick arrows) and AM1-2 (Minster and Jordan, 1978) (thin arrows). Arrow length and shape show the trace a hotspot would make over 50 My. (After Gripp and Gordon, 1990.)

and Iceland have been suggested (Wilson, 1965b; Morgan, 1971). Although the definition is not rigorous, a hot spot is a place where volcanic activity has been taking place for a long period of time (throughout the Cenozoic Era, for instance). It is also a topographic high with a radius of more than, say, 100 km. Long-lived volcanoes in these hot spots may be the outlets of deep-rooted magma associated with mantle plumes that may be regarded immobile compared to surface plates. If this conjecture holds, the age progression of the Hawaii–Emperor Seamount chain could be the result of the absolute

motion of the Pacific Plate, because they may be the trace of the Hawaiian hot spot imprinted on the surface of the Pacific Plate. The most recent plate motion model relative to hot spots is HS2-NUVEL1 (Fig. 10b; Gripp and Gordon, 1990).

Some highlights common to all the plate motion models are: (1) The East Pacific Ridge, among numerous oceanic ridges, shows an especially large spreading rate, reaching 17 cm y^{-1} , while the spreading rate of the Mid-Atlantic Ridge is small at approximately 4 cm y^{-1} ; (2) the absolute velocity of oceanic plates that possess a subduction-type boundary (the Pacific,

Nazca, Cocos Plates) is large, and that of the African and Antarctic Plates, which are surrounded by oceanic ridges, is small. Even though they are not surrounded by oceanic ridges, the absolute velocities of the South and North American Plates and the Eurasian Plate, which have no subduction zones, are small. The Australian–Indian Plate, with Sunda subduction boundary, is moving with considerable speed, although it carries large continents.

Absolute motions can provide us with key information on their driving force. Based on the observations outlined above, Forsyth and Uyeda (1975) demonstrated that, among various possible plate-driving forces, the gravitational pull of the subducted slab is most important. This view now seems to be generally supported.

It is difficult to prove the immobility of hot spots (e.g., Molnar and Stock, 1987). There is another possible model of “absolute” plate motions, which is obtained by imposing no-net-rotation constraint on relative motion model. The most recent of such models is NNR-NUVEL1 (Argus and Gordon, 1991). The difference between the hotspot model and the no-net-rotation model is significant, but not large enough to alter the importance of slab pull in driving plates. Which of the two models is better as motion model relative to the deep mantle is still an unsolved problem.

4.5 What is Lithosphere (Plate)?

A plate is the part of the Earth’s surficial layer that moves the same way as the continents and sea floor. The motion within the mantle, however, cannot be measured at present, so the thickness of the plate defined this way cannot be determined. If a plate moves as a rigid body, perhaps it glides on the softer layer (asthenosphere). The plate may be likened a piece of ice sheet floating on water. It has long been known that below approximately 75 km depth there exists the so-called upper mantle low-velocity zone or LVZ (see Chapter 51 by Lay). The LVZ may also be low in viscosity. Thus, the layer above the LVZ has come to be called the lithosphere (plate) and the LVZ the asthenosphere.

Oceanic plate is also considered as the cooled (hardened) surface boundary layer of the mantle convection system. Various thermal models have been proposed to explain its main features, such as variation of water depth and heat flow with sea floor age, t (e.g., Turcotte and Schubert, 1982). Essentially, early models led to the result that the water depth changes as $\sqrt{t}$ and heat flow as $1/\sqrt{t}$. There were two problems that modelers worried about. One was that $\sqrt{t}$ increase of water depth did not agree with observation for sea floor older than 70 My. It becomes flatter (Parsons and Sclater, 1977). A constant plate thickness model (McKenzie, 1967) and its later variants tried to explain this disagreement, though not so convincingly. The second problem was that the heat flow from young sea floor was much lower than $1/\sqrt{t}$. This problem was solved by the discovery that observed heat flow from young, poorly sedimented

sea floors is biased toward low value because of hydrothermal advective heat transfer that escapes ordinary measurement (see Chapter 81.4 by Cermak). Considering the uncertainty of the real significance of deviations from $\sqrt{t}$ relations, a simple model of a cooling semi-infinite body seems to be adequate at this time (Davis and Lister, 1974; Davies, 1980). Then, the problem becomes the one Lord Kelvin (1863) solved when he calculated the age of the Earth. In the present case, the temperature of the bottom surface of a plate can be that of the solidus or the critical temperature (probably lower than the solidus in general) above which the non-rigid body deformation can occur on the geological time scale. From the Kelvin-type classical solution, the $\sqrt{t}$ laws concerning the plate thickness, water depth, and heat flow, can all be deduced.

5. Plate Tectonic Revolution of Our View of the Earth

5.1 Plate Boundary Processes

There are basically three types of plate boundary: divergent, convergent, and transform fault types. The transform faults displacing mid-oceanic ridges are under water, but the San Andreas Fault in North America, Alpine Fault in New Zealand and North Anatolia Fault in Turkey are the most prominent transform plate boundaries on land characterized by strike-slip seismicity. However, their role in global tectonics is not quite as important as that of divergent and convergent boundaries.

The representatives of divergent plate boundaries are spreading mid-oceanic ridges. The peaks of spreading ridges are approximately 2500 m below sea level. This height roughly represents an equipotential surface, the mantle geoid, as the fluidal asthenosphere is practically exposed there. The width of the mid-oceanic ridges, however, varies drastically, depending on the spreading rate, agreeing with the $\sqrt{t}$ relation. The production of plate is nothing but submarine volcanic activity. This means that most (~80%) of Earth’s volcanic output is occurring at the bottom of the sea. As already mentioned, the results of heat flow measurements in oceanic regions did not agree with the expected $1/\sqrt{t}$ relation. The heat flow was high around the ridge axis, but measured values were scattered widely, and even extremely low values were not rare. In natural science, when theory and observation do not agree, it is customary to doubt the theory. Because plate theory had been so successful in other aspects, however, researchers chose to doubt the observations, and this led them to the right answer—that the ordinary method cannot measure much of the heat released by active hydrothermal circulation within young, heavily fissured oceanic crust (Anderson and Skillbeck, 1981). As the age of the sea floor advances and the impermeable sedimentary cover thickens, the hydrothermal circulation within the crust ceases, and the observed values converge to the theoretical values. Later research,

including observation from deep-sea submersibles, revealed the existence of hydrothermal activity with emission of high-temperature fluids and colonies of organisms such as giant tubeworms on the ridge axis area.

A convergent plate boundary consists of subduction zones and collision zones. In the development of the sea-floor spreading hypothesis, mid-oceanic ridges played a major role. From the global tectonics point of view, however, the role of convergent boundaries is equally important. The idea that continental crust was thrusting over oceanic crust at trenches was introduced in the 1930s (e.g., Griggs, 1939). The seismicity of subduction zones may be summarized as follows (e.g., Yoshii, 1979). Approaching from the ocean side, earthquakes on the oceanic plate are mostly shallow normal-fault type, probably caused by bending. There is occasionally another kind of normal-fault earthquake deeper in the slab, caused probably by tensile forces due to the negative buoyancy of the subducted slab. Sometimes their magnitude becomes 8 class and they seem to tear the plate almost completely (Kanamori, 1971). Thrust earthquakes are very common farther landward, where the depth of the upper surface of the slab reaches 20 km or so. Great earthquakes that occur here are mostly low-angle reverse-fault types, which are attributed to the elastic rebound of the upper plate. These interplate earthquakes do not occur in regions deeper than about 60 km. Mantle earthquakes in the upper plate also cease to occur at about the same depth. These facts prompted Yoshii (1979) to name the boundary between the aseismic and seismic mantle the “aseismic front.” Deeper than about 60 km along the subducting slab, there are Wadati–Benioff zone earthquakes. Their source mechanisms indicate that they are intraplate earthquakes, occurring within the slab itself. The physical mechanism of the deep earthquakes is still not completely clear (Frohlich, 1994; Green and Houston, 1995). The Wadati–Benioff zone under some convergent boundaries has a double structure (Hasegawa *et al.*, 1978).

Compared with seismicity, other thermomechanical aspects, such as igneous activity, heat flow, and backarc basin spreading, are more difficult to explain by subduction models (see, e.g., Bebout *et al.*, 1996). Active volcanoes are distributed in a zone of which the oceanward limit, the “volcanic front,” is well defined. Compared with the igneous rocks on the ocean floor, the arc igneous rocks are much more diverse, reflecting their complicated generation process (e.g., Wyllie, 1988). From simple geophysical point of view, the basic question concerning the arc magmatism is how subduction of a cold oceanic plate could produce temperatures high enough to generate magma in the mantle beneath arcs (e.g., Peacock, 1996). Distribution of heat flow (see Chapter 81.4 by Cermak) raises similar questions. Heat flow is low in the oceanic side of the arc, but high in the landward side, extending throughout the entire backarc basin region. The transition from low to high heat flow zones takes place between the aseismic and the volcanic fronts. How is such a distribution derived by

subduction of a cold plate? The origin of backarc basins such as the Japan Sea and the Philippine Sea is another problem. At least some of them are believed to have been opened by extensional tectonics relatively recently (Cenozoic backarc spreading). Why such extensional tectonics operates in the backarc region is not self-evident. Various models, invoking the effect of friction between converging plates, mantle wedge flow, and dehydration of subducted slab and so forth, have been proposed to try to solve these enigmas.

Under such circumstances, one method of countering the difficulty would be to compare and analyze the characteristics of subduction zones in the world, and examine which factors are effective in which way. This is “comparative subductology” (e.g., Uyeda, 1982). Subduction zones can be classified into two types, depending on whether or not their backarc basins are presently actively spreading: Mariana-type and Chilean-type. Crustal stress, inferred from earthquake source mechanisms, is tensional in the backarc regions of the Mariana-type, while it is compressional in the Chilean-type. Although interplate thrust earthquakes seem to occur similarly at all subduction zones, most of the seismic energy is released at the Chilean-type subduction zones and not at Mariana-type. This fact indicates that mechanical coupling of oceanic and landward plates in the Chilean-type zones is much stronger than that in the Mariana-type. Interestingly, the interplate convergence rate does not seem to greatly affect the strength of coupling. The difference in the mechanical coupling is reflected in many other phenomena and helps in solving the enigmas mentioned above. The two endmember subduction modes may be schematically described as in Figure 11, but what causes such a difference is not entirely clear. A suggestion is that the older the subducting plate, the more advanced its cooling and the higher its density. As a consequence, the subduction would become more “voluntary” and the coupling would weaken, thus creating a Mariana-type subduction zone. This proposal explains the distribution of subduction types—Mariana-types are more common in the Western Pacific and Chilean-types are more common in the Eastern Pacific. An alternative suggestion is that the contrast in the subduction modes between the East and West Pacific margins may stem from the direction of flow in the asthenosphere with respect to the lithosphere; namely, the eastward asthenospheric flow would steepen the dip of the Mariana slab and flatten the Chilean slab (Uyeda and Kanamori, 1979). Since the plate motion models relative to hot spots have a net westward component relative to no-net-rotation models, this mechanism may be viable (Argus and Gordon, 1991; Ricard *et al.*, 1991).

5.2 Orogenesis

During the 18th century, the orthodox school of geological thought was Abraham G. Werner’s (1750–1817) “neptunism” which was challenged by James Hutton’s (1726–1797) “plutonism,” which in turn was challenged by the idea that the great

FIGURE 11 Schematic diagrams showing the two typical modes of subduction. (a) High-stress (Chilean) type; (b) low-stress (Mariana) type.

mountain ranges were created by lateral pressure (Eduard Suess, 1831–1914). Whether the origin of the great mountain ranges is igneous activity or lateral pressure is not completely solved even at present. A concept that played an important role in classical orogenesis was that of “geosyncline” (James Hall (1811–1898), 1859; James Dana (1813–1894), 1873). It was believed that sedimentary layers were formed along with subsidence of long narrow zones, where orogenic activities including igneous and metamorphic processes would eventually occur. The strata would then be deformed, elevated and finally create great mountain ranges. Yet there was no physical mechanism to explain this grand scenario.

Orogenesis based on the idea of a mobilist view of the Earth goes back to Wegener, although he had little support. With the advent of plate tectonics, however, many scientists have energetically attempted to apply this theory to orogenesis. Their theories are similar in principal aspects, but probably the most influential paper was that of Dewey and Bird (1970). In a simplified manner, tectonic conditions seen in today’s Earth

are exhibited in the schematic cross-sectional diagrams in Figure 12. The most basic situation is shown in Figure 12a: The Atlantic Ocean spreads and at the western margin of the South American continent the East Pacific (Nazca) Plate is subducting, and the Andes range is being formed (Cordilleran or Pacific type orogeny). Figure 12b is the cross-section of the Pacific Ocean—also a basic situation: close to its western margin, the trench-island arc-backarc system of Japan develops. Figure 12c is a cross-section of the region from North America (San Andreas fault) to the Mariana Arc, Philippine Sea, and China Sea. If the condition shown in this cross-section persists, the Philippine Sea will eventually disappear and the Mariana Arc and the Philippine Arc will collide unless backarc spreading in the Philippine Sea overcomes the loss due to subduction. If the condition is like Figure 12d, in which the South China Sea subducts eastward, it will be the South China Sea that will disappear. Thus, if the sea floor between continents and/or island arcs subducts, the eventual collision will result (collision type orogeny; Fig. 12g). There are, thus, two basic types of orogenesis: Cordilleran or Pacific-type and collision-type. The causal factors may be mainly thermal (igneous) for the former and dynamic (lateral pressure) for the latter.

As one may recognize from Figure 12, there is a life cycle of oceans. An ocean is born when a continent begins to split and grows by sea-floor spreading (Atlantic stage). When the Atlantic stage ocean spreads, the Pacific Ocean shrinks although sea-floor spreading is going on there, too. The latter is called the Pacific stage, because the Atlantic Ocean will go into this stage after spreading to the extreme. Then the spreading ridge of the Pacific stage ocean will subduct and the sea at last goes into the Mediterranean stage until it is closed by continental collision. When the next continental splitting takes place, the next cycle will start. This concept was presented early in the game (Wilson, 1968b) and was later named the Wilson cycle.

When, during subduction, features like islands, seamounts, plateaus, and oceanic ridges reach trenches, they collide with island arcs or continents. Subduction of a spreading ridge may have significant tectonic effects. If features are too light (buoyant) to subduct, they will accrete to the landward plate, to form the so-called allochthonous terranes, or simply terranes (e.g., Nur and Ben-Avraham, 1982). Even without such salient topographic features, oceanic crust and sediments (terrigenous or pelagic) at the bottom of trenches often accrete, forming an accretionary complex. An accretionary complex is the major agent for the oceanward growth of arcs. Extending these views still farther, geologists have shown that the seemingly extensive one-piece land of Asia is in fact an accumulation of a number of blocks of all sizes called microplates, that have collided and accreted one after another.

One of the prominent facts of today’s collision process is relative lack of truly great earthquakes in collision zones compared with Chilean type subduction zones (Kanamori, 1977). In collision zones where the plates engage tightly, the

FIGURE 12 Schematic sections, showing the major tectonic regimes of the present Earth according to Dewey and Bird (1970).

stress may be high, but a large-scale seismogenic displacement may become more difficult when the coupling gets too tight, probably making truly great earthquakes less frequent. In a sense, a collision zone is no longer an ordinary plate boundary and the stress tends to be relaxed by scattered local fault motions or nonelastic deformation. At the collision zone, the upper plate, that had been an active margin, seems to yield; one typical example is the extrusion tectonics in the region north of the Himalayas and Tibet (Tapponnier *et al.*, 1982). It now seems more appropriate to state the basics of plate tectonics as “plates move without deformation until they meet strong stress,” rather than “plates are rigid.”

6. Beyond Plate Tectonics—Plume Tectonics

Almost all major aspects of orogenic phenomena appear to be explained by plate tectonics. However, it is also evident that plate tectonics can explain the phenomena occurring in the superficial layer of the Earth for only a fraction of its whole history. As well as the long-term secular changes in the global tectonic regime with time scales of billions of years, such events as formation/dispersion of supercontinents (the Wilson cycle) and the Cretaceous pulse of spreading and enhanced magmatism (Large Igneous Province) appear to be difficult to explain by normal steady-state plate tectonics. To understand the whole story, spatial and temporal insights beyond plate tectonics are required. With the aid of new advances in

various fields of earth science, such as ultrahigh-pressure mineral physics, the theory of the origin of the Earth, simulation of mantle convection, and global seismic tomography, what is called “plume tectonics” is emerging. In the following, we will touch upon it, although it is still highly speculative and requires rigorous checking before taken seriously as a new paradigm.

About a decade ago, there was much discussion of two-layered mantle convection vs. whole-mantle convection (see, e.g., Silver *et al.*, 1988). The former was based on mainly geochemical data that appeared to require separate material reservoirs in the mantle, whereas the latter was based on seismological information related to deep penetration of subducted slabs. Upwelling plumes were inferred to rise from the deep mantle to supply magmas to the immobile hot spots. Plumes then were envisaged as thin upwelling jets of columnar shape but were regarded as playing a rather minor role in the whole framework of plate tectonics. Global-scale seismic tomography, pioneered by Adam Dziewonski and colleagues at Harvard University (see, e.g., Chapter 52 by Curtis and Snieder), however, began to clarify the three-dimensional mantle structures at about the same time. Here we refer to global tomography results and their interpretation (Fig. 13) by Fukao (1992) and Fukao *et al.* (1994). There are two low-velocity regions with enormous size (~ 3000 km across) in the lower mantle under the south Pacific and Africa. Moreover, a large region of the lower mantle characterized by high-velocity anomaly exists beneath central Asia where the large amount of subducted oceanic lithosphere has been accumulated. These regions of anomalously low and high velocities are high-temperature upwelling superplumes and low-temperature

FIGURE 13 Schematic cross-section of the Earth showing the global material circulation according to Fukao *et al.* (1994).

downwelling superplumes. Surface expressions of the upwelling superplumes are the well-known superswell in the south Pacific (300 m higher and 2000 km across) and the east African Rift region, both with several hot spots. The superplumes seem to branch into upper mantle plumes for hot spots at the 670 km discontinuity. Whether or not the slabs penetrate through the 670 km transition has long been discussed. Tomographic images show complex behaviors. Slabs behave as if they meet a strong resistance at the 670 km discontinuity, bend horizontally, thicken, and accumulate (the megaliths of Ringwood and Irifune, 1988). The negative Clapeyron P - T slope of the phase transition at the 670 km discontinuity can explain this stagnation behavior. When the volume of the cold stagnant slab material becomes large after continued subduction, it will fall down in big blobs intermittently at some 100–400 My intervals. Numerical modeling supports this view (e.g., Honda *et al.*, 1993).

Maruyama (1994) and Kumazawa and Maruyama (1994), based on these and other data and conjectures encompassing a wide range of earth and planetary science, are rather far-reaching accounts of the new plume tectonics at this stage. The origin of the Pacific superplume may go back to 750–700 Ma, when a supercontinent called Rodinia was broken up. A new ocean, the Pacific, was born in the wakes of the dispersed continental fragments. The African superplume was formed probably when the supercontinent Pangea was rifted ~200 Ma. The present Earth is composed of three domains with different tectonics; they are growth tectonics in the core driven by the energy released from the growing solid inner core, plume tectonics in the lower mantle characterized by large-scale vertical plume movements, and plate tectonics in the upper mantle where horizontal movement of rigid plates dominates. These domains are usually decoupled but are episodically coupled when a massive injection of upper mantle material into the

lower mantle takes place. The steady-state plate movement basically controls the surface dynamics at normal times. The Earth after the Pangean breakup corresponds to this state, except for the Cretaceous pulse period. The intermittent catastrophic avalanche of stagnant slabs at subduction zones, resulting in unusually active sea-floor spreading and magmatism, activates strong mantle convection. This corresponds to the Cretaceous pulse. If catastrophic collapse of the whole downwelling superplume took place, induced mantle overturn would be of global scale. It may occur once in a 400 My or longer time interval, resulting in the formation and breakup of supercontinents. Plume theory says that major events like the Cretaceous pulse and the formation and dispersal of supercontinents were driven by the activation of superplumes, which was triggered by the avalanche of cold slab material into the lower mantle. It is interesting to note that all these geodynamic processes are understood as driven by downgoing cold material, which is inherent to the convective cooling process of the earth. These interesting ideas of “plume tectonics” are, however, still highly speculative at this stage as noted earlier.

Earthquake Mechanisms and Plate Tectonics

Seth Stein and Eryn Klosko
Northwestern University, Evanston, Illinois, USA

1. Introduction

Earthquake seismology has played a major role in the development of our current understanding of global plate tectonics and in making plate tectonics the conceptual framework used to think about most large-scale processes in the solid Earth. During the dramatic development of plate tectonics, discussed from the view of participants by Uyeda (1978, and this volume), Cox (1973), and Menard (1986), the distribution of earthquakes provided some of the strongest evidence for the geometry of plate boundaries and the motion on them (e.g., Isacks *et al.*, 1968). More than thirty years later, earthquake studies retain a central role, as summarized here.

Because earthquakes occur primarily at the boundaries between lithospheric plates, their distribution is used to map plate boundaries and their focal mechanisms provide information about the motion at individual boundaries.

Plate boundaries are divided into three types (Fig. 1). Oceanic lithosphere is formed at *spreading centers*, or mid-ocean ridges, and is destroyed at *subduction zones*, or trenches.

FIGURE 1 Plate tectonics at its simplest. Plates are formed at ridges and subducted at trenches. At transform faults, plate motion is parallel to the boundaries. Each boundary type has typical earthquakes.

Thus, at spreading centers plates move away from the boundary, whereas at subduction zones the subducting plate moves toward the boundary. At the third boundary type, *transform faults*, plate motion is parallel to the boundary. The *slip vectors* of the earthquakes on plate boundaries, which show the motion on the fault plane, reflect the direction of relative motion between the two plates.

The basic principle of plate kinematics is that the relative motion between any two plates can be described as a rotation on a sphere about an *Euler pole* (Fig. 2). Specifically, at any point along the boundary between plates *i* and *j*, with latitude λ and longitude μ , the linear velocity of plate *j* with respect to plate *i* is

$$\mathbf{v}_{ji} = \boldsymbol{\omega}_{ji} \times \mathbf{r} \quad (1)$$

the usual formulation for rigid body rotations in mechanics. The vector $\mathbf{r}$ is the position vector to the point on the boundary,

FIGURE 2 Geometry of plate motions. At any point $\mathbf{r}$ along the boundary between plate *i* and plate *j*, with geographic latitude λ and longitude μ , the linear velocity of plate *j* with respect to plate *i* is $\mathbf{v}_{ji} = \boldsymbol{\omega}_{ji} \times \mathbf{r}$. The Euler pole at latitude θ and longitude ϕ is the intersection of the Euler vector $\boldsymbol{\omega}_{ji}$ with the Earth's surface.

and ω_{ji} is the rotation vector or *Euler vector*. Both are defined from an origin at the center of the Earth.

The direction of relative motion at any point on a plate boundary is a small circle, a parallel of latitude *about the Euler pole* (not a geographic parallel about the North Pole!). For example, in Figure 3a the pole shown is for the motion of plate 2 with respect to plate 1. The first-named plate ($j=2$) moves counterclockwise about the pole with respect to the second ($i=1$). The segments of the boundary where relative motion is parallel to the boundary are transform faults. Thus, transforms are small circles about the pole and earthquakes occurring on them should have pure strike-slip mechanisms. Other segments have relative motion away from the boundary,

FIGURE 3 Relationship of motion on plate boundaries to the Euler pole. Relative motion occurs along small circles about the pole; the rate increases with distance from the pole. Note the difference the sense of rotation makes: ω_{ji} is the Euler vector corresponding to the rotation of plate j counterclockwise with respect to i .

and are thus spreading centers. Figure 3b shows an alternative case. The pole here is for plate 1 ($j=1$) with respect to plate 2 ($i=2$), so plate 1 moves toward some segments of the boundary, which are subduction zones. Note that the ridge and subduction zone boundary segments are not small circles.

The magnitude, or rate, of relative motion increases with distance from the pole, since

$$|\mathbf{v}_{ji}| = |\omega_{ji}| |\mathbf{r}| \sin \gamma \quad (2)$$

where γ is the angle between the Euler pole and the site (corresponding to a colatitude about the pole.) Thus, although all points on a plate boundary have the same angular velocity, the linear velocity varies.

If we know the Euler vector for any plate pair, we can write the linear velocity at any point on the boundary between the plates in terms of the local E-W and N-S components by a coordinate transformation. With this, the rate and azimuth of plate motion become

$$rate = |\mathbf{v}_{ji}| = \sqrt{(\mathbf{v}_{ji}^{NS})^2 + (\mathbf{v}_{ji}^{EW})^2} \quad (3)$$

$$azimuth = 90 - \tan^{-1} \left(\frac{\mathbf{v}_{ji}^{NS}}{\mathbf{v}_{ji}^{EW}} \right) \quad (4)$$

such that azimuth is measured in degrees clockwise from North.

Given a set of Euler vectors with respect to one plate, those with respect to others are found by vector arithmetic. For example, the Euler vector for the reverse plate pair is the negative of the Euler vector

$$\omega_{ij} = -\omega_{ji} \quad (5)$$

Euler vectors for other plate pairs are found by addition

$$\omega_{jk} = \omega_{ji} + \omega_{ik} \quad (6)$$

so, given a set of vectors all with respect to plate i , any Euler vector needed is found from

$$\omega_{jk} = \omega_{ji} - \omega_{ki} \quad (7)$$

For further information on plate kinematics see an introductory text such as Cox and Hart (1986). As discussed there, motions between plates can be determined by combining three different types of data from different boundaries. The rate of spreading at ridges is given by sea-floor magnetic anomalies, and the directions of motion are found from the orientations of transform faults and the slip vectors of earthquakes on transforms and at subduction zones. As is evident, earthquake slip vectors are only one of three types of plate motion data available. Euler vectors are determined from the relative motion data, using geometrical conditions. Since slip vectors and transform faults lie on small circles about the pole, the pole must lie on a line at right angles to them (Fig. 3). Similarly, the

rates of plate motion increase with the sine of the distance from the pole. These constraints make it possible to locate the poles. Determination of Euler vectors for all the plates can thus be treated as an overdetermined least-squares problem, and the best solution found using the generalized inverse to derive *global plate motion models* (Chase, 1972; Minster and Jordan, 1978; DeMets *et al.*, 1990, 1994). Because these models use magnetic anomaly data, they describe plate motion averaged over the past few million years.

New data have become available in recent years due to the rapidly evolving techniques of space-based geodesy. These techniques (Gordon and Stein, 1992) (very long baseline radio interferometry (VLBI), satellite laser ranging (SLR), the global positioning system (GPS), and DORIS (similar to GPS, but using ground transmitters)) use space-based technologies to measure the positions of geodetic monuments to accuracies of better than a centimeter, even for sites thousands of kilometers apart. Hence measurements of positions over time yield relative velocities to precisions almost unimaginable during the early days of plate tectonic studies. A series of striking results, first with VLBI and SLR (e.g., Robbins *et al.*, 1993), and now with GPS (Argus and Heflin, 1995; Larson *et al.*, 1997), show that plate motion over the past few years is generally quite similar to that predicted by global plate motion model NUVEL-1A. This agreement is consistent with the prediction that episodic motion at plate boundaries, as reflected in occasional large earthquakes, will give rise to steady motion in plate interiors due to damping by the underlying viscous asthenosphere (Elsasser, 1969). As a result, the earthquake mechanisms can be compared to the plate motions predicted by both global plate motion models and space-based geodesy.

2. Oceanic Spreading Center Focal Mechanisms

Earthquake mechanisms from the mid-ocean ridge system reflect the spreading process. Figure 4 schematically shows a portion of a spreading ridge offset by transform faults. Because new lithosphere forms at the ridges and then moves away, the relative motion of lithosphere on either side of a transform is in opposing directions. The direction of transform offset, not the spreading direction, determines whether there is right or left lateral motion on the fault. This relative motion, defined as transform faulting, is not what produced the offset of the ridge crest. In fact, if the spreading at the ridge is symmetric (equal rates on either side), the length of the transform will not change with time. This is a very different geometry from a transcurrent fault, where the offset is produced by motion on the fault and the length of the offset between ridge segments would increase with time.

The model is illustrated by focal mechanisms. Figure 5a shows a portion of the Mid-Atlantic Ridge composed of

FIGURE 4 Possible tectonic settings of earthquakes at an oceanic spreading center. Most events occur on the active segment of the transform and have strike-slip mechanisms consistent with transform faulting. On a slow spreading ridge, like the Mid-Atlantic, normal fault earthquakes occur. Very few events occur on the inactive fracture zone.

north–south trending ridge segments, offset by transform faults, such as the Vema Transform, which trend approximately east–west. Both the ridge crest and the transforms are seismically active. The mechanisms show that the relative motion along the transform is right–lateral. Sea-floor spreading on the ridge segments produces the observed relative motion. For this reason, earthquakes occur almost exclusively on the active segment of the transform fault between the two ridge segments, rather than on the inactive extension, known as a *fracture zone*. Although no relative plate motion occurs on the fracture zone it is often marked by a distinct topographic feature, due to the contrast in lithospheric ages across it. Unfortunately, some transform faults named before this distinction became clear, such as the Vema, are known as “fracture zones” along their entire length. Earthquakes also occur on the spreading segments. Their focal mechanisms show normal faulting, with nodal planes trending along the ridge axis.

The seismicity is different on fast spreading ridges. Figure 5b shows a portion of the Pacific–Antarctic boundary along the East Pacific Rise. Here, strike-slip earthquakes occur on the transforms, but we do not observe the ridge crest normal faulting events. These observations can be explained by the thermal structure of the lithosphere, because fast spreading produces younger and thinner lithosphere than slow spreading. The axis of a fast ridge has a larger magma chamber than the slow ridge, and the lithosphere moving away from a fast spreading ridge is more easily replaced than for a slow ridge. Thus, in contrast to the axial valley and normal

faulting earthquakes on a slow ridge, a fast ridge has an axial high and absence of earthquakes.

The mechanisms are consistent with the predictions of plate kinematics. The area in Figure 5a is a portion of the boundary between the South American and Nubian (West African) plates. An Euler vector for Nubia with respect to South America with a pole at 62°N , 37.8°W and a magnitude of $0.328 \text{ degrees My}^{-1}$ predicts that at 0°N , 20°W Africa is moving $\text{N}81^\circ\text{E}$, or almost due East, at 33 mm y^{-1} with respect to South America. The Vema is a boundary segment parallel to this direction, and so is a transform fault characterized by strike-slip earthquakes with directions of motion along the trace of the transform. The short segments essentially at right angles to the direction of relative motion are then spreading ridge segments. The spreading rate determined from magnetic anomalies, and thus the slip rate across the transform, is described by the Euler vector.

FIGURE 5 Maps contrasting faulting on slow and fast spreading centers. (a) The slow Mid-Atlantic ridge has earthquakes both on the active transform and ridge segment. Strike-slip faulting on a plane parallel to the transform azimuth is characteristic. On the ridge segments, normal faulting with nodal planes parallel to the ridge trend is seen. (b) The fast East Pacific Rise has only strike-slip earthquakes on the transform segments. Mechanisms from Engeln *et al.* (1986), Huang *et al.* (1986), and Stewart and Okal (1983).

3. Subduction Zone Focal Mechanisms

Both the largest earthquakes and the majority of large earthquakes occur at subduction zones. Their focal mechanisms reflect various aspects of the subduction process. Figure 6 is a composite cartoon showing some of the features observed in different subduction zones.

Most of the large, shallow, subduction zone earthquakes indicate thrusting of the overriding plate over the subducting lithosphere. The best such examples are the two largest ever recorded: the 1960 Chilean ($M_0 2.7 \times 10^{30}$, $M_s 8.3$) and 1964 Alaskan ($M_0 7.5 \times 10^{29}$, $M_s 8.4$) earthquakes. These were impressive events; in the Chilean earthquake 24 m of slip occurred on a fault 800 km long along-strike and 200 km long down-dip. Smaller, but large, thrust events are characteristic. For example, Figure 7a shows the focal mechanisms of large shallow earthquakes along a portion of the Peru–Chile Trench, where the Nazca Plate is subducting beneath the South American Plate. The mechanisms along the trench show thrust faulting on fault planes with a consistent geometry; parallel to the coast, which corresponds to the trench axis, with shallow dips to the northeast.

These thrust events directly reflect the plate motion. At a point on the trench (17°S , 75°W), global plate motion model NUVEL-1A (DeMets *et al.*, 1994) predicts motion of the Nazca plate with respect to South America at a rate of 68 mm y^{-1} and an azimuth of $\text{N}76^\circ\text{E}$. The direction of motion is toward the trench, as expected at a subduction zone. The major thrust earthquakes at the interface between subducting and overriding plates thus directly reflect the subduction, and slip vectors from their focal mechanisms can be used to determine the direction of plate motion. The rate of subduction is harder to assess. Although the rate can be computed from global plate motion models or space geodesy, not all of the plate motion is always

FIGURE 6 Schematic of some of the features observed at subduction zones. Not all features are seen at all subduction zones.

FIGURE 7 (a) GPS site velocities relative to stable South America (Norabuena *et al.*, 1998), and selected earthquake mechanisms in the boundary zone. Rate scale is given by the NUVEL-1A vector. (b) Cross-section across Andean orogenic system showing velocity distribution inferred from GPS data.

released seismically in earthquakes (Kanamori, 1977). In this case, the seismic slip rate estimated from seismic moments can be only a fraction of the real plate motion. Nonetheless, it is useful to determine the seismic slip rate to assess the fraction of seismic slip, as it reflects the mechanics of the subduction process. It is also interesting to know how this seismic slip varies as a function of time and position along a subduction zone.

Figure 6 also shows other types of shallow subduction zone earthquakes. An interesting class of subduction zone earthquakes result from the flexural bending of the downgoing plate as it enters the trench. Precise focal depth studies show a pattern of normal faulting in the upper part of the plate to a

depth of 25 km and thrusting in its lower part, between 40 and 50 km. These observations constrain the position of the neutral surface separating the upper extensional zone from the lower flexural zone, and thus provide information on the mechanical state of the lithosphere. Occasionally, trenches are the sites of large normal fault earthquakes (e.g., Sanriku 1933 and Indonesia 1977). There has been some controversy whether to interpret these earthquakes as bending events in the upper flexural sheet or as “decoupling” events showing rupture of the entire downgoing plate due to “slab pull.”

The deeper earthquakes, which form the Wadati-Benioff zone, go down to depths of 700 km within the downgoing slab. Their mechanisms provide important information about the physics of the subduction process. The essence of the process is the penetration and slow heating of a cold slab of lithosphere in the warmer mantle. This temperature contrast has important consequences. The subducting plate is identified by the locations of earthquakes in the Wadati-Benioff zone below the zone of thrust faulting at the interface between the two plates. Earthquakes occur to greater depths than elsewhere because the slab is colder than the surrounding mantle. The mechanisms of earthquakes within the slab similarly reflect this phenomenon. The thermal evolution of the downgoing plate and its surroundings is controlled by the relation between the rate at which cold slab material is subducted and that at which it heats up, primarily by conduction as it equilibrates with the surrounding mantle. In addition, adiabatic heating due to the increasing pressure with depth and phase changes contribute.

Numerical temperature calculations show that the downgoing plate remains much colder than the surrounding mantle until considerable depths, where the downgoing slab heats up to the ambient temperature. Comparison of calculated temperatures, the observed locations of seismicity, and images from seismic tomography shows that the earthquakes occur in the cold regions of the slab. The thermal structure also helps explain their focal mechanisms. The force driving the subduction is the integral over the slab of the force due to the density contrast between the denser subducting material and the density of “normal” mantle material outside. This force, known as “slab pull,” is the plate driving force due to subduction. Its significance for stresses in the downgoing plate and for driving plate motions depends on its size relative to the resisting forces at the subduction zone. There are several such forces. As the slab sinks into the viscous mantle, material must be displaced. The resulting force depends on the viscosity of the mantle and the subduction rate. The slab is also subject to drag forces on its sides and resistance at the interface between the overriding and downgoing plates. The latter, of course, is often manifest as the shallow thrust earthquakes.

One way to study the relative size of the negative buoyancy and resistive forces is to use focal mechanisms to examine the state of stress in the downgoing slab. Earthquakes above 300 km generally show stress axes corresponding to extension directed down the slab dip, whereas those below

300 km generally show downdip compression. A proposed explanation is that there are two basic processes operating: near the surface the slab is being extended by its own weight; at depth the slab begins to “run into” stronger material and downdip compression occurs. Another crucial effect may be buoyancy due to mineral phase changes that occur at different depths in the cold slab and in the surrounding mantle. Numerical models of stress in downgoing slabs, using these assumptions, can reproduce the shallow down-dip tension and deep downdip compression (Vassiliou, 1984; Bina, 1996).

Finally, it is worth noting that not all features shown in the schematic (Fig. 6) have been observed at all places. For example, the dips and shapes of subduction zones vary substantially. Some show double planes of deep seismicity; some do not. Even the very large thrust earthquakes, considered characteristic of subduction zone events, are not observed in all subduction zones. In recent years, considerable effort has been made to understand such variations.

4. Diffuse Plate Boundary Earthquake Focal Mechanisms

Although the basic relationships between plate boundaries and earthquakes apply to continental as well as oceanic lithosphere, the continents are more complicated. The continental crust is much thicker, less dense, and has very different mechanical properties from the oceanic crust. Because continental crust and lithosphere are not subducted, the continental lithosphere records a long, involved tectonic history. In contrast, the oceans record only the past 200 million years. One major result of these factors is that plate boundaries in continents are often diffuse, rather than the idealized narrow boundaries assumed in the rigid plate model, which are a good approximation to what we see in the oceans. The initial evidence for this notion comes from the distribution of seismicity and the topography, which often imply a broad zone of deformation between the plate interiors.

FIGURE 8 Comparison of the idealized rigid plate geometry to the broad boundary zones implied by seismicity, topography, or other evidence of faulting. Fine stipple shows mainly subaerial regions where the deformation has been inferred from seismicity, topography, other evidence of faulting, or some combination of these. Medium stipple shows mainly submarine regions where the nonclosure of plate circuits indicates measurable deformation; in most cases these zones are also marked by earthquakes. Coarse stipple shows mainly submarine regions where the deformation is inferred mainly from the presence of earthquakes. These deforming regions form wide plate boundary zones, which cover about 15% of the Earth's surface. The precise geometry of these zones, and in some cases their existence, is under investigation. Plate motions shown are for the NUVEL-1 global relative plate motion model. Arrow lengths are proportional to the displacement if plates maintain their present relative velocity for 25 My. Divergence across mid-ocean ridges is shown by diverging arrows. Convergence is shown by single arrows on the underthrust plate. (After Gordon and Stein, 1992.)

This effect is especially evident in continental interiors, such as the India–Eurasia collision zone in the Himalayas or the Pacific–North America boundary zone in the Western US. Plate boundary zones (Fig. 8), indicated by earthquakes, volcanism, and other deformation, appear to cover about 15% of the Earth's surface (Gordon and Stein, 1992; Stein, 1993).

Insight into plate boundary zones is being obtained by combining focal mechanisms with geodetic, topographic, and geological data. Although plate motion models predict only the integrated motion across the boundary, GPS, geological, and earthquake data can show how this deformation varies in space and time. Both variations are of interest. Possible spatial variations include a single fault system taking up most of the motion (e.g., Prescott *et al.*, 1981), a smooth distribution of motion (e.g., England and Jackson, 1989), or motion taken up by a few relatively large microplates or blocks (e.g., Acton *et al.*, 1991; Thatcher, 1995). Each of these possibilities appears to occur, sometimes within the same boundary zone. The distribution of the motion in time is of special interest because steady motion between plate interiors gives rise to episodic motion at plate boundaries, as reflected in occasional large earthquakes, and in some cases steady creep (Fig. 9). The detailed relation between plate motions and earthquakes is complicated and poorly understood and hence forms a prime target of present studies.

For example, Figure 7a shows focal mechanisms and vectors derived from GPS illustrating the distribution of motion within the boundary zone extending from the stable interior of the oceanic Nazca plate, across the Peru–Chile trench to the coastal forearc, across the high Altiplano and foreland thrust

belt, and into the stable interior of the South American continent. The GPS site velocities are relative to stable South America, so if the South American plate were rigid and all motion occurred at the boundary, they would be zero. Instead, they are highest near the coast and decrease relatively smoothly from the interior of the Nazca plate to the interior of South America. Figure 7b shows an interpretation of these data. In this, about half of the plate convergence ($30\text{--}40\text{ mm y}^{-1}$) is locked at the plate boundary thrust interface, causing elastic strain that is released in large interplate trench thrust earthquakes. Another $18\text{--}30\text{ mm y}^{-1}$ of the plate motion occurs aseismically by smooth stable sliding at the trench. The rest occurs across the sub-Andean fold-and-thrust belt, causing permanent shortening and mountain building, as shown by the inland thrust fault mechanisms. Comparison of strain tensors derived from GPS and earthquake data shows that the shortening rate inferred from earthquakes is significantly less than indicated by the GPS, implying that much of the shortening occurs aseismically. The focal mechanisms also indicate some deformation within the high Andes themselves. There may be some (at most $5\text{--}10\text{ mm y}^{-1}$) motion of a forearc sliver distinct from the overriding plate, a phenomenon observed in some areas where plate convergence is oblique to the trench, making earthquake slip vectors at the trench trend between the trench-normal direction and the predicted convergence direction (McCaffrey, 1992).

Another broad plate boundary zone is the Pacific–North America boundary in western North America. Figure 10 shows the boundary zone, in a projection about the Euler pole. The relative motion is parallel to the small circle shown. Thus the

FIGURE 9 Schematic illustration of the distribution of motion in space and time for a strike-slip boundary zone between two major plates (Stein, 1993).

FIGURE 10 Geometry and focal mechanisms for a portion of the North America-Pacific boundary zone. Dot-dash line shows small circle, and thus direction of plate motion, about the Pacific-North America Euler pole. The variation in the boundary type along its length from extension, to transform, to convergence, is shown by the focal mechanisms. The diffuse nature of the boundary zone is shown by seismicity (small dots), focal mechanisms, topography (1000 m contour shown shaded), and vectors showing the motion of GPS and VLBI sites with respect to stable North America (Bennett *et al.*, 1999; Newman *et al.*, 1999).

boundary is extensional in the Gulf of California, essentially a transform along the San Andreas fault system, and convergent in the eastern Aleutians. The focal mechanisms reflect these changes. For example, in the Gulf of California we see strike-slip along oceanic transforms and normal faulting on a ridge segment. The San Andreas has both pure strike-slip earthquakes (Parkfield) and earthquakes with some dip-slip motion (Northridge, San Fernando, and Loma Prieta) when it deviates from pure transform behavior. The plate boundary zone is also broad, as shown by the distribution of seismicity. Although the San Andreas fault system is the locus of most of the plate

motion and hence large earthquakes, seismicity extends as far eastward as the Rocky Mountains. For example, the Landers earthquake shows strike-slip east of the San Andreas, and the Borah Peak earthquake illustrates Basin and Range faulting. The diffuse nature of the boundary is also illustrated by vectors showing the motion of GPS and VLBI sites with respect to stable North America. Net motion across the zone is essentially that predicted by global plate motion model NUVEL-1A. The site motions show that most of the strike-slip occurs along the San Andreas fault system, but significant motions occur for some distance eastward.

5. Intraplate Deformation and Intraplate Earthquakes

A final important use of earthquake mechanisms is to study the internal deformation of major plates. Although idealized plates would be purely rigid, the existence of intraplate earthquakes reflect the important and poorly understood tectonic processes of intraplate deformation. One such example is the New Madrid area in the central United States, which had very large earthquakes in 1811–1812. The seismicity of such regions is generally thought to be due to the reactivation of preexisting faults or weak zones in response to intraplate stresses. Because motion in these zones are at most a few mm y^{-1} , compared to the generally much more rapid plate boundary motions, seismicity is much lower (Fig. 10). Similarly, major intracontinental earthquakes occur substantially less frequently than plate boundary events; recurrence estimates for 1811–1812 type earthquakes average 500–1000 years. Efforts are being made to combine geodetic data, which indicate deviations from rigidity, to the earthquake data. For example, comparison of the velocities for permanent GPS sites in North America east of the Rocky Mountains to velocities predicted by modeling these sites as being on a single rigid plate shows that the interior of the North American plate is rigid at least to the level of the average velocity residual, less than 2 mm y^{-1} (Dixon *et al.*, 1996; Newman *et al.*, 1999). Similar results emerge from geodetic studies of other major plates, showing that plates thought to have been rigid on geological time scales are quite rigid on decadal scales. Moreover, geological data suggest that such intraplate seismic zones may be active for only a few thousands of years, even though plate motions have been steady for millions of years. As a result, understanding how these intraplate seismic zones operate is a major challenge. A special case of this phenomenon occurs at passive margins, where continental and oceanic lithosphere join. Although these areas are in general tectonically inactive, magnitude 7 earthquakes can occur, as on the eastern coast of North America. Such earthquakes are thought to be associated with stresses at the continental margin, including those due to the removal of glacial loads, which reactivate the faults remaining along the continental margin from the original rifting.

Theoretical Seismology: An Introduction

Agustín Udías

Universidad Complutense de Madrid, Madrid, Spain

1. Introduction

Theoretical seismology is based on the principles and equations of the mechanics of continuous media. This is an idealization in which the granular structure of the materials of the Earth and their molecular and atomic nature are not considered. From this point of view, the Earth is assumed to be an imperfectly elastic, heterogeneous, anisotropic body of approximate ellipsoidal shape in which vibrations are produced by earthquakes. The mathematical analysis of these vibrations is performed by finding adequate solutions for the wave equation. Complete descriptions include the finite dimensions of the Earth and are given by the sum of the normal modes of its eigenvibrations. If wavelengths are small compared to the Earth's dimensions, solutions can be established as propagating waves in an unbounded medium. Flat Earth approximations are sufficient for some problems, while others require the consideration of its nearly spherical shape. In the simplest models, the Earth is considered as a homogeneous, isotropic, perfectly elastic medium. Heterogeneity in the Earth's materials can be treated using layered media with different elastic coefficients or letting these properties vary with the spatial coordinates. Ray theory provides a useful high-frequency approximation to wave propagation in heterogeneous media. In many cases, the assumption of a spherical Earth with radial symmetry provides a close approximation to the real situation, but more realistic models must include three-dimensional heterogeneities. Lack of perfect elasticity is accounted for by introducing dissipation of energy and attenuation factors. As a first approximation, isotropic models are adopted, but further analysis needs to consider anisotropic conditions. By proceeding through these successive modifications in Earth models, its imperfect elasticity, heterogeneity, and anisotropy can be adequately considered.

The generation of earthquakes is considered by the theory of source mechanisms. The processes of fracture on near-surface geological faults or of other types at greater depths are

represented by mechanical models of increasing complexity. When observations at long distance and low frequencies are used, the source can be represented by simple models consisting of systems of forces or dislocations acting at a point. In this case, the first-order seismic moment tensor provides a useful description of a general type of point source. Dimensions of the source and rupture propagation can be treated from kinematic and dynamic approaches. In a more complete description, complex dynamic models with variable distributions of stress and friction on the rupture surface provide more realistic descriptions of earthquake source processes. Theoretical seismology starts with the recognition by J. Michell in 1761 and T. Young in 1807 that motion produced by earthquakes propagates in the Earth in the form of waves with finite velocity. Developments in the theory of elasticity by, among others, Bernoulli, Euler, Navier, Poisson, Cauchy, Stokes, Lord Rayleigh, Lamb, Volterra, and Love, began to be applied to the problems of seismic wave generation and propagation by the first generation of seismologists such as Oldham, Wiechert, Omori, Mohorovičić, Zöppritz, and Herglotz and later, before 1939, by Gutenberg, Jeffreys, Bullen, Nakano, Stoneley, and others (Ben Menahem, 1995). Theoretical developments of seismology after 1939 are summarized in chronological order by Ben Menahem (1995). The theory of seismology can be found in the general seismology textbooks such as Macelwane and Sohon (1936), Bullen (1947), Sawarensky and Kirnos (1960), Pilant (1979), Aki and Richards (1980), Ben Menahem and Singh (1981), Bullen and Bolt (1985), Lay and Wallace (1995), Dahlen and Tromp (1998), and Udías (1999). References not given in this chapter can be found in these texts.

In this chapter the most basic concepts necessary for the understanding of the excitation and propagation of elastic waves in the Earth are presented. More advanced developments and special topics can be found in other chapters of this Handbook; for example, seismic ray theory in Chapter 9 by Chapman, scattering and attenuation of seismic waves in

Chapter 13 by Sato, Fehler, and Wu, and earthquake dynamics in Chapter 12 by Madariaga and Olsen.

2. The Earth as an Imperfectly Elastic Medium

2.1 Constitutive Relations

The first approximation to the mechanical behavior of the Earth's material is that corresponding to an elastic body. According to Hooke's law, for a perfect elastic body and infinitesimal deformations, stress and strain are linearly related. Cauchy's formulation is given by the tensor relation

$$\tau_{ij} = C_{ijkl}e_{kl} \quad (1)$$

where τ_{ij} is the stress tensor, e_{kl} is the infinitesimal strain tensor, and C_{ijkl} is the fourth-order tensor of elastic coefficients. Repeated subindices are summed over their three values. The strain energy is given by

$$W = \frac{1}{2} C_{ijkl}e_{ij}e_{kl} \quad (2)$$

In terms of the derivatives of the elastic displacements, since due to the symmetry of τ_{ij} and e_{kl} , $C_{ijkl} = C_{klij}$, Eq. (1) gives

$$\tau_{ij} = C_{ijkl}u_{k,l} \quad (3)$$

where the comma in the subscript represents partial derivatives with respect to the coordinates indicated by the following index. For a heterogeneous medium the components of C_{ijkl} are functions of the space coordinates. For a perfect elastic body in the general case, the tensor has 21 independent elements. If in the medium there is some kind of symmetry, the number of independent components is reduced. For example, for orthorhombic symmetry it is reduced to 9, for hexagonal symmetry to 5, and for cubic symmetry to 3. A simplifying assumption is that of isotropy, where the coefficients are reduced to two:

$$C_{ijkl} = \lambda\delta_{ij}\delta_{kl} + \mu(\delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk}) \quad (4)$$

where λ and μ are Lamé coefficients, μ is the shear modulus, and λ is related to the bulk modulus K , which relates changes in volume to applied normal stresses, $K = (\tau_{11} + \tau_{22} + \tau_{33})/3(e_{11} + e_{22} + e_{33})$. According to Eq. (2), the strain energy is given by

$$W = \frac{1}{2} \lambda (e_{11} + e_{22} + e_{33})^2 + \mu e_{ij}e_{ij} \quad (5)$$

Most problems in seismology can be solved considering the Earth as an isotropic medium. Furthermore, equations are simplified for the special case of $\lambda = \mu$ (Poisson solid), approximately satisfied in the materials of the Earth's interior. Although deviations from isotropy are small, they are observed in wave propagation in the Earth. Many problems

can be approximated by assuming hexagonal symmetry. In this case, there are five elastic coefficients, A , C , F , L , and N (Love, 1945). This symmetry has a principal axis and is called transverse symmetry since any direction normal to this axis has the same properties. Strain energy for a transverse isotropic medium is given by

$$W = \frac{1}{2} A (e_{11}^2 + e_{22}^2) + \frac{1}{2} C e_{33}^2 + F (e_{11} + e_{22}) e_{33} + (A - 2N) e_{22} e_{11} + \frac{1}{2} L (e_{13}^2 + e_{31}^2) + N e_{12}^2 \quad (6)$$

Imperfect elasticity of Earth's materials is a consequence of energy dissipation in its deformation due to internal friction. One way to introduce the nonelastic behavior is to add a viscous component of deformation where stress depends on the time rate of strain. Mechanical viscoelastic models have the viscous element in series (Kelvin–Voigt body), in parallel (Maxwell body), or both (standard linear solid). The effect of the viscous element is to introduce a relaxation time (T) into the stress–strain relation. In the case of the standard linear solid, strain is relaxed with relaxation time T_e under constant stress and stress is relaxed with T_t under constant strain.

Another way to introduce anelasticity is to make the elastic coefficients complex numbers. For an isotropic medium the shear and bulk moduli are

$$\mu' = \mu + i\mu^*, \quad K' = K + iK^* \quad (7)$$

The real and imaginary parts of μ' are related to the quality factor Q that is a measure of the energy lost in wave propagation:

$$\frac{1}{Q_\mu} = 2 \left(\frac{\mu^*}{\mu} \right)^{1/2} \quad (8)$$

In a similar manner we can define Q_K . In the viscoelastic models Q can be related to the relaxation times and the frequency ω of the harmonic excitation; for a standard linear solid this is given by

$$\frac{1}{Q} = \frac{\omega(T_e - T_t)}{1 + \omega^2 T_e T_t} \quad (9)$$

The elastic and anelastic properties of Earth's materials are usually represented by the elastic coefficients and the quality factor.

2.2 The Equation of Motion

The dynamic behavior of an elastic body is given by the equation of motion (Newton's second law). For a volume V surrounded by a surface S (Fig. 1), according to Euler's formulation, this equation is given by

$$\int_V F_i dV + \int_S T_i dS = \frac{d}{dt} \int_V \rho v_i dV \quad (10)$$

FIGURE 1 Elastic medium of volume V surrounded by surface S , forces $\mathbf{F}$, and displacements $\mathbf{u}$ at each element of volume and stress $\mathbf{T}$ at each element of surface of normal $\mathbf{v}$. (From Udías, 1999.)

where $\mathbf{F}$ are forces acting at volume elements dV or body forces, $\mathbf{T}$ are stresses (tractions) acting across surface elements dS , and $\mathbf{v}$ is the velocity at each point of the volume (Fig. 1). Expressing the vector $\mathbf{T}$ by the tensor τ_{ij} , using $T_i = \tau_{ij}\nu_j$, where ν_j is the normal to the surface element dS , and applying Gauss's theorem to the surface integral to convert it into a volume integral, we obtain, for an infinite medium with density constant with time, the differential equation

$$\frac{\partial \tau_{ij}}{\partial x_j} + F_i = \rho \frac{dv_i}{dt} \quad (11)$$

This equation can be written in terms of elastic displacements by the substitution of Eq. (3), approximating the total time derivatives by partial ones in the Lagrangian formulation,

$$\frac{\partial}{\partial x_j} (C_{ijkl} u_{k,l}) + F_i = \rho \frac{\partial^2 u_i}{\partial t^2} \quad (12)$$

For an isotropic material, substituting Eq. (4) in Eq. (12), we obtain

$$[\lambda \delta_{ij} u_{k,k} + \mu (u_{i,j} + u_{j,i})]_{,j} + F_i = \rho \ddot{u}_i \quad (13)$$

where the dots represent the time derivatives. Equations (12) and (13) are the fundamental second-order differential equations for the elastic displacements in an infinite medium for the general case [Eq. (12)] and isotropic conditions [Eq. (13)]. In heterogeneous media, these equations include the spatial derivatives of the elastic coefficients and are very difficult to solve. For a homogeneous medium, we can write Eq. (13), in vector form:

$$(\lambda + \mu) \nabla (\nabla \cdot \mathbf{u}) + \mu \nabla^2 \mathbf{u} + \mathbf{F} = \rho \ddot{\mathbf{u}} \quad (14)$$

This expression, known as the Navier equation, represents the equation of motion in terms of displacements for a continuous,

homogeneous, isotropic, infinite, elastic medium. This equation can be easily transformed into

$$\alpha^2 \nabla (\nabla \cdot \mathbf{u}) - \beta^2 \nabla \times (\nabla \times \mathbf{u}) + \frac{\mathbf{F}}{\rho} = \ddot{\mathbf{u}} \quad (15)$$

In this equation we have introduced the parameters α and β whose values in terms of the elastic coefficients are

$$\alpha^2 = \frac{\lambda + 2\mu}{\rho} = \frac{K + \frac{4}{3}\mu}{\rho} \quad (16)$$

$$\beta^2 = \frac{\mu}{\rho} \quad (17)$$

The parameter α is related to the divergence of $\mathbf{u}$ and in consequence to changes in volume and β to the curl of $\mathbf{u}$, that is, to changes in form without changes in volume. Equations (14) and (15), if there are no body forces ($\mathbf{F} = 0$), become homogeneous Navier differential equations.

Equation (15) can be separated into two equations each depending only on α or β using the potential functions for the displacements and the forces, according to Helmholtz's theorem,

$$\mathbf{u} = \nabla \phi + \nabla \times \boldsymbol{\psi} \quad (18)$$

$$\mathbf{F} = \nabla \Phi + \nabla \times \boldsymbol{\Psi} \quad (19)$$

where ϕ and Φ are scalar potentials and $\boldsymbol{\psi}$ and $\boldsymbol{\Psi}$ vector potentials with zero divergence. Applying Eqs. (18) and (19) to Eq. (15) we obtain

$$\alpha^2 \nabla^2 \phi + \frac{\Phi}{\rho} = \frac{\partial^2 \phi}{\partial t^2} \quad (20)$$

$$\beta^2 \nabla^2 \boldsymbol{\psi} + \frac{\boldsymbol{\Psi}}{\rho} = \frac{\partial^2 \boldsymbol{\psi}}{\partial t^2} \quad (21)$$

The vector differential equation of motion [Eq. (14) or (15)] is now expressed in terms of the potentials by a scalar and a vector equation of a much more simple form. Equation (20) is related to the elastic perturbations that imply changes in volume, and Eq. (21) to perturbations with only changes in form. This separation of the equation of motion is very important, because it greatly facilitates its solution. Unfortunately, this is only possible in homogeneous media.

Equations (14), (15), (20), and (21) are second-order differential equations for partial derivatives of the displacements or their potentials with respect to spatial coordinates and time with an independent term formed by the body forces or their potentials. If we specify these forces, the solution of these equations gives us the elastic displacement field for an infinite homogeneous isotropic medium. These equations are very important in seismology, since many problems can be solved using this approximation.

2.3 The Green Function and the Representation Theorem

The solution of many problems in seismology can be formulated using the Green function of elastodynamics, which represents the response of the medium to a unit impulsive force in space and time with arbitrary direction. This force may be represented mathematically by means of the Dirac delta function:

$$\mathbf{F}_n(x_j, t) = \delta(x_j - \xi_j) \delta(t - \tau) \mathbf{e}_n \quad (22)$$

The force $\mathbf{F}_n$ is applied at the point of coordinates ξ_j and time τ , is null outside this point and time, and its orientation is given by the unit vector $\mathbf{e}_n$. If we substitute this force in the equation of motion (10), its solutions are the elastic displacements for every point of coordinates x_j for every time t , given by a second-order tensor $G_{ni}(x_j, \xi_j, t, \tau)$, where subindex n refers to the direction of the exciting force. Replacing stress in terms of the derivatives of the displacements (3) for a homogeneous medium in the equation of motion (10), we obtain

$$\int_V \rho \ddot{\mathbf{G}}_{ni} dV - \int_S C_{ijkl} G_{nk,l} v_j dS = \int_V \delta(x_s - \xi_s) \delta(t - \tau) \delta_{ni} dV \quad (23)$$

The solutions of Eq. (23) are the Green functions of the medium and depend on its characteristics, elastic coefficients and density, shape of volume V , and boundary conditions on S . For each medium there is a different Green function that describes how this medium reacts mechanically to an impulsive excitation and is, therefore, a proper characteristic of each medium.

The Green function can be used to find the elastic displacements in a medium corresponding to a specified system of body forces in an alternative way to solving the equation of motion (11). For this purpose we use the Green–Volterra formulation of Betti's reciprocity theorem. Assuming causality conditions, that is, that the medium is at rest until a time when motion starts, the elastic displacements at each point of the volume V are given by

$$u_n(x_s, t) = \int_{-\infty}^{\infty} d\tau \int_V F_i G_{ni} dV + \int_{-\infty}^{\infty} d\tau \int_S (G_{ni} T_i - C_{ijkl} u_i G_{nk,l} v_j) dS \quad (24)$$

This equation is generally referred to as the representation theorem. It gives us the elastic displacements inside a volume V as the sum of two double integrals over time and space. The first is the volume integral of the body forces multiplied by the Green function and the second the surface integral of the stress (tractions) across each element dS multiplied by the Green function plus the displacements times the derivatives of the Green function (Fig. 2). Equation (24) allows us to determine elastic displacements produced by a system of body forces defined in a volume or by a system of stresses and

FIGURE 2 Forces acting inside a volume and stresses and displacements at its surface and displacements $\mathbf{u}$ at any point in terms of Green's function. (From Udías, 1999.)

displacements defined over a surface by means of the appropriate Green functions. In this equation, which is very useful in source studies and the generation of synthetic seismograms, the Green function acts as a propagator which propagates the effects of forces, stresses, or displacements defined on coordinates (ξ_i, t) to determine the elastic displacements in points of coordinates (x_i, t) . In general, the determination of Green's function is not an easy problem. The most simple case is for an infinite, homogeneous, isotropic, elastic medium, but solutions for other media such as layered half-space or a radially symmetric sphere have been determined and can be computed numerically.

3. Seismic Waves

3.1 Wave Equations and Their Solutions

Equations (20) and (21) in the absence of body forces become wave equations, where the parameters α and β are the wave velocities. The wave equation can be written in a general form, for a velocity c as,

$$\nabla^2 f(x_i, t) = \frac{1}{c^2} \frac{\partial^2}{\partial t^2} f(x_i, t) \quad (25)$$

The dependence on time of Eq. (25) can be eliminated if f has a harmonic dependence on time:

$$f(x_i, t) = \hat{f}(x_i) e^{-i\omega t} \quad (26)$$

Substituting in Eq. (25), we obtain Helmholtz's equation,

$$(\nabla^2 + k^2) \hat{f}(x_i) = 0 \quad (27)$$

where $k = \omega/c$ is the wavenumber. For harmonic waves, the form of the solutions of Eq. (27) depends on the geometry of the wave front and can be found expressing the Laplacian in Cartesian, cylindrical, or spherical coordinates.

In Cartesian coordinates, solutions for monochromatic waves of frequency ω can be written as

$$f(x_1, x_2, x_3, t) = A \exp\{i[k(x_1\nu_1 + x_2\nu_2 + x_3\nu_3) - \omega t + \varepsilon]\} \quad (28)$$

Waves propagate in the direction of the unit vector ν_i (normal to the wave front) with velocity $c = \omega/k$. The wavenumber can be separated into its three components, $k_i = k\nu_i$. This solution represent waves with plane wave fronts of infinite extension, which implies that their source is at an infinite distance. This condition does not correspond to any real problem; however, if we are interested only in wave propagation and can assume that the source is at very great distance, plane waves are a good approximation in the far field.

Many problems of wave propagation in seismology—for example, those concerning surface waves—have axial symmetry and are solved using cylindrical coordinates. For the most general cases with dependence on the three coordinates, $f(r, \phi, z, t)$, using the method of separation of variables, solutions are given in terms of $J_n(k_r r)$ (Bessel functions of order n) and harmonic functions of z , ϕ , and t . The wavenumber has components in the z and r directions and $k^2 = k_r^2 + k_z^2$. The general solution is given by the sum over all values of n . For symmetry with respect to ϕ and large values of r , we can express Bessel functions in asymptotic form in terms of harmonic functions, obtaining

$$f(r, z, t) = \left(\frac{2}{\pi k_r r}\right)^{1/2} A \exp\left[i\left(k_r r + k_z z - \omega t - \frac{\pi}{4}\right)\right] \quad (29)$$

In this equation, we find the dependence of wave amplitudes with the inverse of the square root of the distance r . Wave fronts are cylindrical surfaces whose areas increase with increasing r , and energy generated at the source is distributed over an increasing area. As a consequence, amplitudes per unit area decrease with distance. This decrease of amplitude with distance is called “geometric spreading.” This term has not appeared in plane waves, since their wave fronts are always infinite planes and their source is at an infinite distance.

Propagation of seismic waves generated at a point leads to the consideration of spherical waves $f(r, \theta, \phi, t)$. In spherical coordinates for propagating waves, complex solutions are given by

$$f(r, \theta, \phi, t) = A_{nm} \left(\frac{2k}{\pi}\right)^{1/2} h_n(kr) P_n^m(\cos \theta) \exp[i(\pm m\phi - \omega t)] \quad (30)$$

where $h_n(kr) = j_n(kr) + in_n(kr)$, are Hankel spherical functions, ($j_n(kr)$ and $n_n(kr)$ are Bessel spherical functions of first and

second kind) and $P_n^m(\cos \theta)$ the Legendre associate functions. As in the previous case, the general solution is the sum for all values of n and m . For each value of n , there are values of m from $m = -n$ to $m = n$. For symmetry with respect to ϕ and large values of r , using the asymptotic expression for $h(kr)$ in terms of harmonic functions, the solution may be written approximately as,

$$f(r, \theta, t) = A_n \frac{1}{r} \left(\frac{2}{k\pi}\right)^{1/2} P_n(\cos \theta) \exp\left[i\left(kr - \omega t - \frac{n+1}{2}\pi\right)\right] \quad (31)$$

Wave amplitudes decay with distance as $1/r$, which is the geometrical spreading factor for spherical waves.

Seismic waves are not monochromatic harmonic waves, but are usually pulses of different shapes or trains of waves with different frequencies. Waves with an arbitrary dependence of time can be represented by the sum or integral of harmonic waves of different frequencies using Fourier's theorem. For plane waves,

$$f(x_i, t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} F(\omega) \exp\{i[k(\omega)\nu_k x_k - \omega t]\} d\omega \quad (32)$$

where $F(\omega)$ is a complex function termed the complex spectrum of $f(x_i, t)$ and can be represented as

$$F(\omega) = R(\omega) + iI(\omega) = A(\omega)e^{i\Phi(\omega)} \quad (33)$$

where $A(\omega)$ is the amplitude spectrum and $\Phi(\omega)$ is the phase spectrum. These two functions of frequency represent the contributions of each harmonic component to the amplitude and initial phase of the resulting function of time. Phase velocity $c(\omega) = \omega/k(\omega)$ is now a function of frequency, that is, each harmonic component may have different phase velocity. Motion due to a propagating wave at a point is given by a function of time, $f(t)$. The same information can be represented as a function of frequency $F(\omega)$, that is, obtained by means of the Fourier integral

$$F(\omega) = \int_{-\infty}^{\infty} f(t)e^{-i\omega t} dt \quad (34)$$

where $f(t)$ is a real function that represents amplitudes of waves at each time for a particular point of space. Its Fourier transform $F(\omega)$ is a complex function that can be represented by its amplitudes $A(\omega)$ and initial phases $\Phi(\omega)$ for each frequency. In this way, problems of wave propagation can be studied in the domain of time or frequency.

3.2 Body Waves

According to Eqs. (20) and (21) we obtain for an infinite homogeneous isotropic elastic medium two types of waves with velocities α and β . Since the potential ϕ is related to the

divergence of the displacement $\mathbf{u}$ and $\boldsymbol{\psi}$ to its curl, α is the velocity of longitudinal waves (P waves) and β that of transverse or shear waves (S waves). Since these waves travel inside the medium, they are called body waves. The total elastic displacement of body waves $\mathbf{u}$ is the sum of the displacements of P and S waves, $\mathbf{u} = \mathbf{u}^P + \mathbf{u}^S$. In terms of the potentials (18), they can be written as

$$\mathbf{u}^P = \nabla \phi \quad (35)$$

$$\mathbf{u}^S = \nabla \times \boldsymbol{\psi} \quad (36)$$

Depending on the geometry of the problem, we will have solutions for the potentials ϕ and $\boldsymbol{\psi}$, like those discussed above [Eqs. (28) to (31)], with wavenumbers $k_\alpha = \omega/\alpha$ and $k_\beta = \omega/\beta$. For line sources and cylindrical waves, amplitudes decrease with distance as $1/\sqrt{r}$ and for point sources and spherical waves as $1/r$.

Displacement components of P and S waves in the Earth are usually referred to geographical axes (North, East, Down) (u_1^P, u_2^P, u_3^P) and (u_1^S, u_2^S, u_3^S). The S -wave displacement is on a plane normal to the ray and can be separated into two components SH (on the horizontal plane and normal to the ray) and the SV (on the incidence or vertical plane). The unit vectors $\mathbf{r}$ (direction of the ray), $\mathbf{SH}$ and $\mathbf{SV}$ form a system of axes in respect of which the displacement vector is (u_P, u_{SH}, u_{SV}).

It is convenient for many problems to separate the P - SV motion from the SH motion, selecting the plane (x_1, x_3) as the plane containing the ray. The components of displacements of P - SV motion (u_1 and u_3), can be expressed in terms of scalar potentials ϕ and ψ , the SH displacement (u_2) being kept apart:

$$u_1 = \phi_{,1} - \psi_{,3} = u_1^P + u_1^{SV} \quad (37a)$$

$$u_3 = \phi_{,3} - \psi_{,1} = u_3^P + u_3^{SV} \quad (37b)$$

Since the ray is contained in plane (x_1, x_3), we can define c as the apparent velocity of propagation in the direction of x_1 , and write

$$\phi = (Ae^{ikrx_3} + De^{-ikrx_3}) \exp[ik(x_1 - ct)] \quad (38a)$$

$$\psi = (Be^{iksx_3} + Ee^{-iksx_3}) \exp[ik(x_1 - ct)] \quad (38b)$$

$$u_2 = (Ce^{iksx_3} + Fe^{-iksx_3}) \exp[ik(x_1 - ct)] \quad (38c)$$

where, r and s are given by

$$r = \sqrt{\frac{c^2}{\alpha^2} - 1} = \tan e = \cot i \quad (39)$$

$$s = \sqrt{\frac{c^2}{\beta^2} - 1} = \tan f = \cot j \quad (40)$$

where e and f are the angles of emergence and i and j are the angles of incidence for P and S waves, respectively. For real values of r and s ($c > \alpha > \beta$), waves propagate in the

x_3 direction, up and down, with apparent velocities c/r and c/s , respectively.

3.3 Reflection and Refraction

The presence in an elastic medium of any kind of surface across which there are changes in the properties, and especially, of a free surface, introduces a series of phenomena that must be considered in the study of wave propagation. First, there are body-wave reflections and refractions; that is, in the surface separating two media, the energy of incident waves is partly reflected into the same medium and partly transmitted or refracted into the second medium.

If e and f are the angles of emergence of incident and reflected P and S waves in medium M of velocities, α , β and e' , f' are those of refracted or transmitted waves in medium M' with velocities α' and β' , then Snell's law is given by (Fig. 3)

$$\frac{\cos e}{\alpha} = \frac{\cos f}{\beta} = \frac{\cos e'}{\alpha'} = \frac{\cos f'}{\beta'} = \frac{1}{c} = p \quad (41)$$

where p is the ray parameter. As a function of the velocities, tangents of e and f are given by Eqs. (39) and (40). Reflection R and transmission T coefficients are given by the ratios of incident to reflected or refracted amplitudes and are found applying the boundary conditions at the surface of separation of the two media, namely, continuity of stress and displacement. Equations relating incident amplitudes to those transmitted and reflected are known as Zöppritz's equations. For SH waves and incidence from M to M' : $R_{SH} = C/C_0$ and $T_{SH} = C'/C_0$, where C_0 is the incident amplitude, C reflected and C' transmitted or refracted [in the notation of Aki and Richards (1980), $R_{SH} = \hat{S}\hat{S}$ and $T_{SH} = \hat{S}\hat{S}'$]. The matrix expressing the total SH motion transmitted and reflected between two elastic media

FIGURE 3 Incident P wave and reflected and refracted P and S waves. (From Udías, 1999.)

with incidence from both media (R'_{SH} and T'_{SH} for waves traveling from M' to M , equivalent to $\hat{S}\hat{S}$ and $\hat{S}\hat{S}'$), or the scattering matrix, is given by

$$\mathbf{SH} = \begin{pmatrix} R_{SH} & R'_{SH} \\ T_{SH} & T'_{SH} \end{pmatrix} \quad (42)$$

In a similar way for P and SV incident waves, we have the reflection and refraction coefficients,

$$R_{PP} = \frac{A}{A_0}; \quad R_{PS} = \frac{B}{A_0}; \quad T_{PP} = \frac{A'}{A_0}; \quad T_{PS} = \frac{B'}{A_0} \quad (43a)$$

$$R_{SS} = \frac{B}{B_0}; \quad R_{SP} = \frac{A}{B_0}; \quad T_{SS} = \frac{B'}{B_0}; \quad T_{SP} = \frac{A'}{B_0} \quad (43b)$$

The scattering matrix for the general P – SV motion generated in two elastic media in contact with incident waves traveling in both directions has 16 elements: 8 for incident P and SV waves traveling from medium M and another 8 for those traveling from medium M' .

$$\mathbf{P-SV} = \begin{pmatrix} R_{PP} & R_{SP} & R'_{PP} & R'_{SP} \\ R_{PS} & R_{SS} & R'_{PS} & R'_{SS} \\ T_{PP} & T_{SP} & T'_{PP} & T'_{SP} \\ T_{PS} & T_{SS} & T'_{PS} & T'_{SS} \end{pmatrix} \quad (44)$$

$\mathbf{SH}$ and $\mathbf{P-SV}$ scattering matrices can be combined into a total 6×6 matrix. Reflection and transmission coefficients for incident P and S waves in isotropic media are functions of the elastic coefficients λ and μ , and density ρ of the two media and their angles of incidence. Equations are simplified for the case when $\lambda = \mu$.

Under certain conditions, for angles of incidence greater than the critical, r or s become imaginary ($c < \alpha$, or $c < \beta$). Then waves represented by Eqs. (39) to (41) do not propagate in the x_3 direction but only along a direction parallel to the surface (x_1) and their amplitudes decrease with depth from the surface. These waves are called inhomogeneous or evanescent waves. For example, for P waves traveling from M to M' , if $\alpha' > \alpha$, $\sin(i_c) = \alpha/\alpha'$, where i_c is the critical angle. Incident waves with $i > i_c$ are not transmitted into medium M' , but are totally reflected into medium M (total reflection). However, inhomogeneous waves do appear in medium M' . The reflection and transmission coefficients represent amplitude quotients (displacements for SH and potentials for P – SV) and must be modified to represent the energy partition at the boundary. The analysis of these phenomena is very important for the interpretation of seismic reflection–refraction data in studies of the Earth's structure.

3.4 Surface Waves

A phenomenon related to the presence of surfaces separating media of different characteristics, and especially of a free surface, is the generation of what, in general, are called surface waves. These waves are produced by constructive

interference of body waves in connection with such surfaces. To generate surface waves we need at least two types of waves that can interfere in a constructive way. Their main characteristics are that they propagate parallel to the surface and their amplitudes decrease with depth from the surface. In seismology, the most important are those related to the presence of the Earth's free surface and those that are also affected by other surfaces of contact between layers of different elastic properties in its interior.

The most basic problem is the study of the existence of surface waves in an elastic, homogeneous half-space. Since we are considering surface waves, their amplitudes must decrease with depth ($-x_3$) [in Eqs. (39) to (41), $A = B = C = 0$, and r and s must be both imaginary ($c < \beta < \alpha$)]. The boundary conditions are that the three stress components across the free surface (tractions) must be null. For the τ_{32} component the condition leads to $F = 0$, and in this case surface waves do not have transverse component (u_2). The other two conditions ($\tau_{31} = \tau_{33} = 0$) lead to two homogeneous equations whose solution require that the determinant of the system must be null. This condition results in the Rayleigh equation for the phase velocity c , namely

$$\left(2 - \frac{c^2}{\beta^2}\right)^2 = 4\sqrt{1 - \frac{c^2}{\alpha^2}}\sqrt{1 - \frac{c^2}{\beta^2}} \quad (45)$$

For $\lambda = \mu$ ($\alpha = \sqrt{3}\beta$), the solution compatible with the existence of surface waves ($c/\beta < 1$) is $c = 0.9194\beta$, the phase velocity of Rayleigh waves. These waves have displacement components u_1 and u_3 , shifted in phase by $\pi/2$, with elliptical particle motion with vertical major axis and amplitude decreasing with depth (Fig. 4).

FIGURE 4 Particle motion of Rayleigh waves in a half-space and dependence of displacement components with depth. (From Udías, 1999.)

The propagation of surface waves in layered media of isotropic material with a free surface introduces new elements with respect to the half-space problem. Inside each layer there may exist waves traveling upward and downward, so that in Eqs. (39) to (41) s is real and r is real or imaginary and in the half-space both r and s must be imaginary. Boundary conditions are null stress components across the free surface, and continuity of displacement and stress across the surfaces of contact between layers and the last layer and the half-space. The solutions result, first, in two types of waves with different velocity, Rayleigh (P - SV) and Love (SH). Second, phase velocities depends on frequency $c(\omega)$, that is, waves are dispersed. Third, there are different modes of propagation due to the relation between layer thickness and wavelengths.

The above-mentioned characteristics appear in the basic problem of a single layer over a half-space. For a layer of S velocity β' , rigidity μ' , and thickness H over a half-space of velocity β and rigidity μ with $\beta > \beta'$, the solution of the problem for the SH displacement results in the existence of Love waves with phase velocity c ($\beta > c > \beta'$) that satisfies the dispersion equation

$$\frac{\mu \sqrt{1 - c^2/\beta^2}}{\mu' \sqrt{c^2/\beta'^2 - 1}} = \tan\left(kH \sqrt{c^2/\beta'^2 - 1}\right) \quad (46)$$

The phase velocity of Love waves is a function of frequency, $c(\omega)$, or wavenumber, $c(k)$. Since the tangent function has positive values between zero and infinity for different intervals of its argument (the first between 0 and $\pi/2$, the second between π and $3\pi/2$, and so on), each of them corresponds to a mode of propagation, the fundamental mode to the first interval ($0 < kHs' < \pi/2$) and higher modes to the rest. Higher modes have a cut-off frequency and their displacements inside the layer have a number of nodes equal to the mode number (Fig. 5).

The problem for P - SV motion in a layer over a half-space is more complicated and its outcome is the existence of Rayleigh waves. The dispersion equation follows from the expansion of a 6×6 determinant resulting from the six boundary conditions (null stress components at the free surface and continuity of stress and displacement between the layer and the half-space). Phase velocity is a function of frequency and modes are now separated into pairs of symmetric and antisymmetric modes. Limits of Rayleigh wave phase velocity for the fundamental mode are $\beta > c > \beta'$ and for higher modes $c_R > c > c'_R$ (c_R and c'_R are the Rayleigh wave velocities corresponding to the half-space and the layer).

The multilayer problem involves solving the equations resulting from the boundary conditions, free stresses across the free surface, and continuity of stress and displacement at each boundary, with r and s imaginary in the half-space. The problem is formulated in matrix form according to the Thomson-Haskell method or using the propagator matrix

FIGURE 5 Dispersion curves for Love waves in a layer over a half-space for fundamental (FM) and higher modes (HM). (From Udías, 1999.)

(Section 3.6). Surface waves in spherically stratified media introduce certain modifications into the phase velocities with respect to the flat case.

3.5 Wave Dispersion. Phase and Group Velocity

We have seen that surface waves in layered media are dispersed, that is, their phase velocity is a function of frequency (or period). Then, they are formed by trains of waves, with different frequencies arriving at different times. Arrival times, amplitudes, and phases for each frequency depend on the dispersion equation [for example, Eq. (46)]. If phase velocity is a function of frequency $c(\omega)$ and we can also write $k(\omega)$ and $\omega(k)$, then the group velocity corresponding to the velocity of energy propagation is given by $U = d\omega/dk$ and in terms of the phase velocity,

$$U = c + k \frac{dc}{dk} \quad (47)$$

Amplitudes of dispersed waves are a function of frequency and can be written as in Eq. (32) as an integral over all frequencies. In the integrand, the amplitude $F(\omega)$ varies very slowly compared with the variation of the phase ($\Phi(\omega) = kx - \omega t$). Then the integral has only significant values for frequencies corresponding to stationary values of the phase, that is, for $d\Phi/d\omega = 0$. For a wave propagating in the x direction, taking derivatives of the phase with respect to the frequency we obtain

$$\frac{d\Phi}{d\omega} = \frac{d}{d\omega}(kx - \omega t) = \frac{x}{U} - t \quad (48)$$

For the frequency ω_0 that makes the phase stationary ($d\Phi/d\omega = 0$), the group velocity is $U = x/t$. Group velocity is, then,

FIGURE 6 Phase and group velocity curves and a dispersed wave train. (From Udías, 1999.)

the velocity corresponding to the frequency that makes the phase stationary for a given distance and time. Using the principle of stationary phase, the integral of Eq. (32) for waves propagating in the x direction with variable phase velocity $c(k)$ results in

$$u(x, t) = A(k_0) \left[\frac{2\pi}{u \frac{dU}{dk}} \right]^{1/2} \cos\left(k_0 x - \omega_0 t \pm \frac{\pi}{4}\right) \quad (49)$$

Then, for a given time and distance, energy is contained in a harmonic wave of wavenumber k_0 and frequency ω_0 , values corresponding to the stationary phase. Since dU/dk is in the denominator, largest amplitudes correspond to $dU/dk = 0$ (minimum of the group velocity curve), or the Airy phase (Fig. 6).

3.6 Wave Propagation in Layered Media

Many problems of wave propagation in seismology, not only propagation of surface waves, can be solved by representing the Earth as a stratified or layered medium, that is, formed by layers of a certain thickness and with different mechanical properties. For certain problems we can use a flat approximation of parallel horizontal layers and the problem is reduced to two dimensions. Layers of constant properties may be considered as an approximation for media where elastic coefficients vary in continuous form with depth. In layered or stratified media, problems are presented in discrete form and may be treated using matrix formulation (Kennett, 1983). In this formulation, we make use of the displacement–stress vector and, as in Eqs. (39) to (41), we separate the vertical and

the horizontal dependence of propagation. Considering only the dependence with depth, putting $z = x_3$, for SH and P – SV we can write,

$$\mathbf{SH} = [u_2(z), \tau_{32}(z)] \quad (50)$$

$$\mathbf{P-SV} = [u_1(z), u_3(z), \tau_{31}(z), \tau_{33}(z)] \quad (51)$$

It can be shown that the derivatives with respect to z of the components of the displacement–stress vector are linear functions of the same components. The fundamental equations for the development of matrix methods of resolution of wave propagation in layered media are based on this property and can be written in a general matrix form as,

$$\frac{d\mathbf{b}(z)}{dz} = \mathbf{A}(c, z)\mathbf{b}(z) \quad (52)$$

where $\mathbf{b}$ is the displacement–stress vector defined in Eqs. (50) and (51) and $\mathbf{A}$ is a square matrix whose elements depend on the elastic parameters and density of the medium functions of depth ($\alpha(z)$, $\beta(z)$, $\rho(z)$), frequency ω and horizontal velocity c . In the case of layers of constant properties within each layer, the only variables are c and ω . The displacement–stress vector at a level z_n is related to that of a reference level z_0 by means of a so-called propagator matrix $\mathbf{P}(z, z_0)$ by

$$\mathbf{b}(z_n) = \prod_{i=1}^n \mathbf{P}(z_i, z_{i-1})\mathbf{b}(z_0) \quad (53)$$

The propagator matrix $\mathbf{P}$ is related to the solution of Eq. (52) and, in general, it can be computed numerically. The matrix formulation is a powerful method for solving wave propagation problems in layered media such as surface waves and SH and P – SV reflected and refracted waves.

4. Ray Theory

In a heterogeneous medium, elastic coefficients and density, and consequently wave velocities, are functions of the spatial coordinates. In Eqs. (12) and (13) we will have derivatives of the elastic parameters, resulting in complicated expressions even for isotropic media. If we assume that elastic properties change very slowly, so that over a distance of one wavelength the wave velocity changes much less than the wave velocity itself, then, we can use the approximation of ray theory. Ray theory is a powerful method used extensively in seismology for the study of the Earth's interior and calculation of synthetic seismograms. In this section a very short introduction is given to its basic principles. An extended treatment of the subject can be found in Chapter 9 by Chapman. Ray theory is a high-frequency approximation for the solution of the wave equation that holds for media with properties that vary very

slowly. Under these conditions we can write an approximate wave equation such as Eq. (25), where $c(x_i)$ is a function of coordinates. For harmonic time dependence, according to Eq. (27), we have

$$\left(\nabla^2 + \frac{\omega^2}{c^2(x_i)} \right) u(x_i) = 0 \quad (54)$$

Solutions of this equation can be written as

$$u(x_i) = A(x_i) \exp[i\omega T(x_i)] \quad (55)$$

where the amplitudes $A(x_i)$ and the travel times $T(x_i)$ are functions of the coordinates. Ray theory approximation implies that spatial gradients of A and T are small in comparison with the functions themselves. Solutions to this problem in terms of ray theory are given by the eikonal equation and the WKBJ (Wentzel, Kramers, Brillouin, and Jeffreys) method. Substituting Eq. (55) into Eq. (54), with the approximation $|A''/A| \ll \omega/c$, we obtain

$$\left(\frac{\partial T}{\partial x_1} \right)^2 + \left(\frac{\partial T}{\partial x_2} \right)^2 + \left(\frac{\partial T}{\partial x_3} \right)^2 = \frac{1}{c^2} \quad (56)$$

This equation is known as the eikonal equation or the equation of Hamilton's characteristic functions. The equation relates the value of the square of the gradient of the travel time at a point of a medium of variable velocity to the square of the inverse of the velocity c at the same point. The velocity c is in the direction normal to the wave fronts or along the ray. Since the gradient of the wave front $S(x_i) = \omega T(x_i)$ represents the direction of propagation or ray trajectory, Eq. (56) shows how this trajectory changes as wave fronts propagate through a medium of variable velocity. If we know how c varies in the medium, the eikonal equation can be used to trace the rays.

4.1 Ray Paths and Travel Times

In a spherical medium where velocity varies continuously with the radius according to Snell's law and the Benndorf relation, we can write for each point on a ray,

$$\frac{r \sin i}{v} = p = \frac{dt}{d\Delta} \quad (57)$$

where i is the incident angle at a point of radial distance r where velocity is v and $t(\Delta)$ is the travel time at angular distance Δ . In the point of the ray path where it turns upward, $i = \pi/2$ and $r_p/v_p = p$. In terms of the slowness η (defined as $\eta = r/v$), $p = \eta_p$. Equation (57) relates the velocity distribution $v(r)$ with the ray path $i(r)$ and the travel times $t(\Delta)$. By integration we can obtain expressions for angular distance Δ and travel time t in terms of the velocity distribution. If the focus is at the surface

FIGURE 7 Ray path in a spherical medium with velocity increasing with depth. (From Udías, 1999.)

we obtain (Fig. 7),

$$\Delta = 2 \int_{r_p}^{r_0} \frac{p \, dr}{r \sqrt{\eta^2 - p^2}} \quad (58)$$

$$t = 2 \int_{r_p}^{r_0} \frac{\eta^2 \, dr}{r \sqrt{\eta^2 - p^2}} \quad (59)$$

These expressions are the fundamental equations of kinematic ray theory. They allow the calculation of theoretical travel times $t(\Delta)$ from velocity models of the Earth with radial symmetry, $v(r)$, and the inversion of observed data of travel times to obtain the corresponding velocity distributions.

5. Normal Mode Theory

We have seen that perturbations produced in an unbounded elastic body have the form of waves that propagate in its interior. If the medium is perfectly elastic, homogeneous and isotropic, there are only two types of waves (P and S), which propagate with constant velocities (α and β) that depend on the elastic coefficients and density with no conditions imposed on their frequency. The Earth has finite dimensions and is bounded by a free surface; therefore, we have to consider the elastic behavior of an elastic body of finite dimensions. This consideration leads us into normal mode theory or free oscillations of the Earth (see also Chapter 10 Lognonné and Clévedé).

From the point of view of free oscillations, the Earth reacts to an earthquake by vibrating as a whole, in the same way as a bell when struck. Vibrations of a finite elastic body are the sum of an infinite number of modes (harmonics) that correspond to frequencies with values proportional to the inverse of the body characteristic dimension. For an elastic body of finite dimensions, wave propagation and free vibrations are two different approaches to the study of the same phenomenon. If wavelengths are very small compared with the

dimensions of the body, we can approximate the problem by wave propagation in an unbounded medium, but we cannot if they are not so. Free eigenvibrations or normal mode theory includes the complete phenomenon, but for short wavelengths we need a sum of many modes, which is not very practical. Thus, in seismology, wave propagation is used for high frequencies and normal modes for lower ones. The study of the Earth's free oscillations is based on the theory of vibrations of an elastic sphere. The problem increases in complexity as we proceed from an isotropic homogeneous sphere to models with radial distribution of elastic parameters and density, three-dimensional heterogeneities, and lack of perfect elasticity, and those that include the effects of gravity, rotation, and ellipticity.

A first approximation to the problem of free oscillations of the Earth is that of a homogeneous elastic sphere. The problem is solved in spherical coordinates where displacements are derived from a scalar Φ and a vector ψ potential as we saw in Eq. (18). Vector potential ψ can be separated into two potentials that are products of the unit vector in the radial direction and a scalar potential,

$$\psi = \nabla \times S\mathbf{r} + T\mathbf{r} \quad (60)$$

$$\mathbf{u} = \nabla\Phi + \nabla \times \nabla \times S\mathbf{r} + \nabla \times T\mathbf{r} \quad (61)$$

In Eq. (61), displacements are now separated into three parts, the first term (Φ) representing P -wave motion, the second (S) SV and the third (T) SH . In relation to surface waves, Φ and S represent Rayleigh-wave motion and T Love wave. Thus, S is called spheroidal potential and T toroidal potential.

In the absence of body forces and without considering rotation and gravity, Navier's equation (15) is given by

$$\alpha^2 \nabla(\nabla \cdot \mathbf{u}) - \beta^2 \nabla \times \nabla \times \mathbf{u} = \ddot{\mathbf{u}} \quad (62)$$

The problem is solved in spherical coordinates by expressing $\mathbf{u}$ in terms of potentials Φ , S , and T according to Eq. (61). This leads for the harmonic time dependence (26) to Helmholtz equations (27) for Φ , S , and T . As in Section 3.1, real solutions for standing waves convergent at the origin (the center of the Earth) are given in terms of Bessel spherical functions $j_n(kr)$, Legendre associate functions $P_n^m(\cos\theta)$, and harmonic functions $e^{\pm im\phi}$. As a consequence, we obtain for potential Φ , a solution as a sum,

$$\Phi(r, \theta, \phi) = \sum_{l=0}^{\infty} j_l(k_\alpha r) \sum_{m=-l}^l Y_l^m(\theta, \phi) \quad (63)$$

where

$$Y_l^m(\theta, \phi) = (-1)^m \left[\frac{2l+1}{4\pi} \frac{(l-m)!}{(l+m)!} \right] P_l^m(\cos\theta) \times [C_l^m \cos m\phi + S_l^m \sin m\phi] \quad (64)$$

are the associate spherical harmonic functions of index (l, m) . Similar expressions are found for S and T depending on k_β . Subindex l is the angular and m is the azimuthal number. For each value of l there are $2l+1$ values of m . The solution for each value of l and m is called a mode of oscillation and the general solution is the sum over all their values. The problem is separated into toroidal modes involving potential T and spheroidal modes involving Φ and S . Thus we have toroidal modes T_l^m and spheroidal modes S_l^m of oscillation.

5.1 Toroidal Modes

The part of the problem corresponding to potential $T(r, \theta, \phi, t)$ leads to toroidal modes T_l^m or modes of SH motion. Boundary condition at the free surface of the sphere ($r = a$) is $\tau_{r\phi} = 0$. This condition leads to a relation for the part of the solution depending on Bessel spherical functions that may be written for a homogeneous medium as

$$x j_{l+1}(x) = (l-1) j_l(x) \quad \text{for } x = k_\beta a \quad (65)$$

This equation has an infinite number of solutions, for which we use subindex n . Thus, boundary conditions introduce a third index in the problem. For each value of l , the first value of n ($n=0$) corresponds to the fundamental mode and the rest to higher modes, harmonics, or overtones, and modes are represented by ${}_n T_l^m$.

For toroidal modes index l refers to the order of Legendre associate functions and consequently to the distribution of displacements on spherical surfaces depending on angle θ . For $l=1$, the fundamental mode implies whole-body oscillations around the axis origin of θ , which are not possible as free vibrations. They are possible for higher modes since internal parts oscillate in different senses and there are no changes in total angular momentum. For $l=2$ each hemisphere oscillates in an opposite sense, and for higher values ($l > 3$) there are as many zones oscillating in opposite senses as the order number of the mode (Fig. 8). Index m refers to the dependence of displacements on azimuthal angle ϕ and takes values from $-l$ to l . Index n refers to the number of roots in the r dependence of displacements for each configuration of l and m . For a homogeneous sphere, eigenfrequencies do not depend on index m . Thus, different displacements, according to values of m , correspond to the same frequencies; that is, the problem presents degeneracy. The same happens if elastic properties depend only on the radius, but not for the completely heterogeneous problem.

Theoretical values for eigenperiods of toroidal modes have been calculated for different models of the Earth, generally with radial symmetry. The longest period (43.82 min for a particular Earth model) corresponds to the fundamental mode of the second-order mode ${}_0 T_2$. With increasing order number, mode periods decrease in value.

FIGURE 8 Spheroidal S_0 , S_2 , and S_3 and toroidal modes T_1 , T_2 , T_3 . (From Udías, 1999.)

5.2 Spheroidal Modes

The problem of spheroidal modes implies solutions for potentials Φ and S and displacements correspond to P - SV motion. Boundary conditions at the free surface are that the stresses are null ($\tau_{rr} = \tau_{r\theta} = 0$). Solutions for potentials Φ and S are of the type of Eqs. (63) and (64). As in the case of toroidal modes, spheroidal modes are represented by ${}_nS_l^m$. For the lowest order $l=0$, according to Eq. (63), potentials Φ and S are functions only of r . Then there are only displacements u_r , and $u_\theta = u_\phi = 0$. These modes are called radial modes. The fundamental mode ${}_0S_0$, corresponds to an expansion and contraction of the sphere without changing its form. For higher values of n , there are inside the sphere as many nodal surfaces at which the motion is null and changes sign, as the order number.

For $l=1$, the fundamental mode ${}_0S_1$ does not exist, since a displacement of the center of mass is not possible in free vibrations. However, there are values for the higher modes ${}_1S_1$, ${}_2S_1$, etc. For $l=2$, displacements are symmetric with respect to the plane normal to the axis from which the angle θ is measured. The Earth takes an ellipsoidal form, alternately flattened and elongated at the poles (Fig. 8). Fundamental mode ${}_0S_2$ has the lowest frequency of all modes (53.80 min for a particular Earth model) and no nodes of displacement in the interior of the sphere. For higher modes ($n > 1$), as in toroidal modes, there are in the interior of the sphere a number of nodal surfaces equal to the order of the mode. The longest period corresponds to mode ${}_0S_2$, which is greater than the period of corresponding toroidal mode ${}_0T_2$. Thus, this is the longest period for free oscillations of the Earth. For a mode of the same order, periods of spheroidal modes are longer than those of toroidal modes.

5.3 Nonspherical Symmetry

The Earth has properties that we have not treated in the above discussion. First, we have the effect of gravity, which affects mainly the spheroidal modes. Second, the presence of a liquid core results in spheroidal modes with periods significantly different from those in models without such a core and the existence of toroidal modes only in the mantle. This influence is greater for low-order modes. These two effects do not change the spherical symmetry of the problem.

Three additional effects that break the spherical symmetry derive from the Earth's rotation, the ellipticity of its shape, and its lateral heterogeneity (dependence of the elastic properties and density on θ and ϕ). The problem is no longer degenerate and the values of eigenfrequencies are modified. For each value of l and n , there are now several values of frequencies depending on the index m with a maximum of $2l+1$, which are called multiplets. The most important of these effects is a consequence of the Earth's rotation, which introduces centrifugal and Coriolis forces, which have axial symmetry. This effect produces splitting of eigenfrequencies. If angle ϕ is measured on a plane normal to the Earth's rotation axis, a perturbation, due principally to Coriolis force, displaces eigenfrequencies associated to modes of angular order l by a quantity related to the index m and to the angular frequency of the Earth's rotation. This effect is small for high eigenfrequencies and can only be observed in low frequencies.

Two other effects are due to the Earth's ellipticity and to deviations of elastic properties and density from radial symmetry. These effects are small and also produce splitting in eigenfrequencies. If the lack of radial symmetry in the Earth's composition were very large, besides splitting of eigenfrequencies we could have a coupling of toroidal and spheroidal modes. Although their effects are small, heterogeneities in the Earth's composition can be detected in the analysis of free oscillations.

6. Effects of Anisotropy and Anelasticity in Wave Propagation

6.1 Anisotropy

Consideration of the influence of the lack of isotropy or anisotropy in wave propagation in the Earth has recently become an important subject of seismology and can be related to geodynamic processes. Although deviations from the conditions of isotropy are small, their effect on the propagation of seismic waves can be observed and provide important information (Babuska and Cara, 1991; Chapter 53 by Cara). Hexagonal or cylindrical symmetry is often assumed in seismological problems. As discussed in Section 2.1, this symmetry, called transverse isotropy, has a principal axis and properties in any direction normal to this axis are the same. The elastic tensor has five independent components, namely, A , C , F , L , and N .

Wave propagation in an isotropic medium with hexagonal symmetry has the following properties. For waves propagating along the principal axis of symmetry (x_3), there are two values of velocity, which correspond to P and S waves, namely, $\alpha = \sqrt{C}/\rho$ and $\beta = \sqrt{L}/\rho$. Wave propagation in this case is similar to that of an isotropic medium. For waves propagating in a direction (x_1) perpendicular to the principal axis (x_3), there are three different waves, namely, P waves with velocity $\alpha = \sqrt{A}/\rho$, different from that of waves propagating along the principal axis, and two types of S waves with different velocities, $\beta_1 = \sqrt{N}/\rho$ (displacement in x_2 direction) and $\beta_2 = \sqrt{L}/\rho$ (displacement in x_3 direction) (Fig. 9). If x_3 is the vertical direction, for waves traveling in x_1 direction, SH and SV components propagate with different velocities and are two different waves. This phenomenon is known as S -wave splitting, since SV and SH components arrive with a time delay between them. Due to this type of symmetry, this phenomenon takes place for any orientation of propagation in the plane normal to the principal axis.

FIGURE 9 Propagation of P and S waves in an anisotropic medium with hexagonal symmetry (x_3 principal axis) for rays traveling along the principal axis and a perpendicular direction. (From Udías, 1999.)

In general, for any type of anisotropy, there are always three types of body waves propagating with three different velocities. Choosing the three components of displacement appropriately, they are called quasi- P , quasi- SH and quasi- SV waves. Velocities for these three types of waves change according to the type of symmetry present in the medium. According to these properties, anisotropy can be detected by observations of changes in P -wave velocity along two perpendicular directions and by observations of S -wave splitting.

The main effect of anisotropy on surface waves is that they cannot always be separated into Rayleigh and Love waves as in isotropic media. Radial and transverse components of motion are coupled, forming generalized dispersed surface waves that are a combination of Rayleigh and Love waves. We can distinguish three main effects of anisotropy in the propagation of surface waves. First, there is a discrepancy in the relation between the phase velocities of Rayleigh and Love waves with respect to those in isotropic media. Second, there are discrepancies in the phase velocities found for trajectories along different azimuths in the same region. Third, there is a departure of the polarization plane of Rayleigh waves from the vertical orientation.

6.2 Anelasticity

Wave propagation in imperfectly elastic media results in the attenuation of the amplitudes of wave motion (Fig. 10). Attenuation can be expressed in terms of the quality factor $Q(\omega)$, in general, a function of frequency, that is defined as

$$\frac{1}{Q(\omega)} = \frac{1}{2\pi} \frac{\Delta E}{E} \quad (66)$$

Thus, $1/Q$ represents the ratio between the elastic energy ΔE dissipated during one cycle of harmonic motion of frequency ω and the maximum or the mean energy E accumulated in the same cycle.

Wave attenuation can also be considered by assigning complex values to frequency and wavenumber, $k' = k + ik^*$ and $\omega' = \omega - i\omega^*$. In this form we can now define the quality factors of propagation in time and space, Q_t and Q_s , in terms of the imaginary parts of frequency or wavenumber:

$$\frac{1}{Q_t} = \frac{2\omega^*}{\omega} \quad (67)$$

$$\frac{1}{Q_s} = \frac{2k^*}{k} \quad (68)$$

From this it follows that phase velocity ($c' = \omega'/k'$) also has complex values, $c' = c + ic^*$. Attenuation of body waves can then also be expressed by taking complex values for velocities of P and S waves, namely, $\alpha' = \alpha + i\alpha^*$ and $\beta' = \beta + i\beta^*$. Since observations of the attenuation of body waves are measured from amplitudes at different distances, the imaginary

FIGURE 10 Amplitude attenuation due to anelasticity during a period. (From Udías, 1999.)

part of velocity is related to the spatial quality factor Q_s . In a similar way as in Eqs. (67) and (68), we can define quality factors for P and S waves as, $1/Q_\alpha = 2\alpha^*/\alpha$ and $1/Q_\beta = 2\beta^*/\beta$. These factors are related to Q_μ and Q_K [Eq. (8)] that are defined in a similar way, giving complex values to coefficients μ and K . For values of Q_α and Q_β larger than unity this relation is

$$\frac{1}{Q_\beta} = \frac{1}{Q_\mu} \quad (69)$$

$$\frac{1}{Q_\alpha} = \frac{4}{3} \left(\frac{\beta}{\alpha} \right)^2 \frac{1}{Q_\mu} + \left[1 - \frac{4}{3} \left(\frac{\beta}{\alpha} \right)^2 \right] \frac{1}{Q_K} \quad (70)$$

In most seismological problems, it is assumed that there is no dissipation of energy in purely compressive or dilatational processes and therefore $Q_K = \infty$. Then, for $\lambda = \mu$, $Q_\alpha = \frac{9}{4} Q_\beta$.

In the ray theory approximation, we are interested in attenuation with distance along the ray path. Amplitude attenuation of a monochromatic P wave of frequency ω is given by

$$A = A_0 \exp\left(-\frac{\omega s}{2\alpha Q_\alpha}\right) = A_0 \exp(-\omega t^*) \quad (71)$$

where A and A_0 are amplitudes at two points separated by a distance s along the ray path. For a homogeneous medium, $t^* = t/2Q_\alpha$, where $t = s/\alpha$ is the travel time of P waves. A similar relation can be written for S waves using β and Q_β . In a spherical medium of radial symmetry with velocity $v(r)$, and quality factor $Q(r)$, both depending on the radius, for a ray with surface focus and ray parameter p along the complete path, we obtain

$$t^* = \int_{r_p}^{r_0} \frac{\eta(r)^2 dr}{rQ(r)\sqrt{\eta(r)^2 - p^2}} \quad (72)$$

where $\eta(r)$ is the slowness ($\eta = r/v$). If $\bar{Q}$ is the mean value of $Q(r)$ along the ray and t is the travel time, an approximation is $t^* = t/(2\bar{Q})$. In the Earth, for surface foci and epicentral distances between 30° and 90° , t^* is practically constant with a value of 1 sec for P waves and 4 sec for S waves; that is, S waves attenuate faster than P waves.

Anelastic attenuation of surface waves with distance and time can be expressed by coefficients γ_s and γ_t , related to spatial and temporal quality factors by $\gamma_s = \omega/2cQ_s$ and $\gamma_t = \omega/2Q_t$. Since, in a dispersed wave, energy propagates with group velocity U , for amplitudes corresponding to instantaneous frequencies, phase velocity must be substituted by group velocity. Then, the relation between Q_t and Q_s is

$$\frac{1}{Q_t} = \frac{U}{c} \frac{1}{Q_s} \quad (73)$$

For dispersed waves, temporal and spatial quality factors are different.

The influence of anelasticity on the free oscillations of the Earth affects the peaks of the spectral amplitudes. In a perfectly elastic medium, spectral peaks for each mode are delta functions at corresponding frequencies. In the presence of anelasticity, the spectrum has maximum amplitudes for each mode centered at the corresponding frequency $n\omega_l$ with a certain width $\Delta\omega$ (width of the spectrum when its amplitude is half its maximum value). The quality factor is related to the width of the spectral peak by $1/Q_t = \Delta\omega/n\omega_l$. Since attenuation increases with $1/Q$, the larger the attenuation, the wider the peaks of the spectrum. This is, in fact, a very general effect and can also be applied to observations in the time domain of propagating pulses in imperfectly elastic media.

7. Representation of the Source Mechanism

In seismology the problem of the source mechanism consists in relating observed seismic waves to the parameters that describe the source. In the direct problem theoretical seismic wave displacements are determined from source models, and in the inverse problem parameters of source models are derived from observed wave displacements. The first step in both problems is to define the seismic source by a mechanical model that represents the physical phenomena that corresponds to a fracture in the Earth's crust. These models or representations of the source are defined by parameters whose number depends on its complexity (Kasahara, 1981; Kostrov and Das, 1988; Koyama, 1997).

7.1 Green and Sommigliana Tensors

The representation theorem [Eq. (24)] gives the elastic displacement in terms of the Green tensor. As we saw, this tensor

corresponds to the displacements of an impulsive force acting at a point. Then, finding solutions for the Green tensor is the first step in solving the problem of source mechanism. The simplest case of the Green tensor is that corresponding to an infinite, homogeneous isotropic elastic medium,

$$G_{ij} = \frac{1}{4\pi\rho} \left[\frac{1}{r^3} (3\gamma_i\gamma_j - \delta_{ij}) \int_{r/\alpha}^{r/\beta} \tau \delta(t-\tau) d\tau + \frac{1}{r\alpha^2} \gamma_i\gamma_j \delta\left(t - \frac{r}{\alpha}\right) - \frac{1}{r\beta^2} (\gamma_i\gamma_j - \delta_{ij}) \delta\left(t - \frac{r}{\beta}\right) \right] \quad (74)$$

where the force is in an arbitrary direction indicated by the index j , γ_i are the direction cosines of the line from the source to the observation point, and r the distance. The right side of Eq. (74) is composed of three terms: The first depends on $1/r^3$ and on both α and β ; this is called the near field, since it decays rapidly with distance. The second and third terms depend on $1/r$; they constitute the far field and each depends only on α or β . Then, P and S motion is mixed in the near field and separated in the far field. Equation (74) is a very important result in elastodynamics that gives the elastic displacement field for the most fundamental type of source and medium. It constitutes the basic building block in seismic source studies.

A similar fundamental problem is the static solution for a constant force acting at a point in an arbitrary direction. For an infinite, homogeneous, isotropic, elastic medium and a unit force, static displacements are given by,

$$S_{ij} = \frac{1}{8\pi\rho r} \left[\left(\frac{1}{\beta^2} - \frac{1}{\alpha^2} \right) \gamma_i\gamma_j + \left(\frac{1}{\beta^2} + \frac{1}{\alpha^2} \right) \delta_{ij} \right] \quad (75)$$

Subindex j indicates the direction of the force and, as in Eq. (74), displacements are given by a tensor. This expression, known as the Somigliana tensor, is the fundamental equation in elastostatics. The Somigliana tensor can be considered as the limit of the Green tensor for infinite time and the static terms come only from the near-field displacement.

7.2 Equivalent Body Forces

The first mathematical formulation of the mechanism of earthquakes was presented by Nakano in 1923, using ideas already developed by Lamb and Love. Nakano used the point source approximation, valid if observation points are at a sufficiently long distance compared with source dimensions and long wavelengths. Thus, he represented the source by a system of body forces acting at a point. Since these forces must represent the phenomenon of fracture, they are called equivalent forces.

The problem may be stated as follows. Let us consider an elastic medium of volume V surrounded by a surface S . In its interior there is a small region of volume V_0 , surrounded by a surface Σ , that we will call the focal region, where fracture takes place (Fig. 11). This process can be represented by

FIGURE 11 Focal region V_0 , forces $\mathbf{f}$, stresses $\mathbf{T}$; and displacements $\mathbf{u}$ outside the focal region. (From Udías, 1999.)

a distribution of body forces $\mathbf{F}(\xi_i, t)$ acting per unit volume inside V_0 . If it is assumed that no other body forces are present (gravity, etc.), and that on its surface S stresses and displacements are null, using the representation theorem in terms of the Green tensor [Eq. (24)], the elastic displacements in an infinite medium are given by

$$u_i(x_s, t) = \int_{-\infty}^{\infty} d\tau \int_{V_0} F_k(\xi_s, \tau) G_{ki}(x_s, t; \xi_s, \tau) dV \quad (76)$$

The Green tensor $\mathbf{G}$ acts as a “propagator” of the effects of forces $\mathbf{F}$, from the points where they are acting (ξ_i inside V_0) to points x_i outside V_0 where elastic displacements u_i are produced. For a point source at the origin of coordinates we have

$$u_i(x_s, t) = \int_{-\infty}^{\infty} F_k(\tau) G_{ki}(x_s, t - \tau) d\tau \quad (77)$$

Elastic displacements are given now by the time convolution of the forces acting at the focus with the Green function for the medium. Internal sources must be in equilibrium so that they should satisfy the condition that their resulting total force and moment are null. If we want to represent the shear motion at a fault, the equivalent system of forces is that of two couples with no resulting moment or double-couple (DC) model (Fig. 12). If the couples are oriented in the direction of unit vector $\mathbf{l}$ and $\mathbf{n}$, where $\mathbf{n} \cdot \mathbf{l} = 0$, and their moment is $M = sF$, where s is the arm of the couple, displacements are given by

$$u_i^{DC} = \int_{-\infty}^{\infty} M(l_k n_l + n_k l_l) G_{ik, l} d\tau \quad (78)$$

FIGURE 12 Double-couple model and equivalent system of pressure and tension forces. (From Udías, 1999.)

An equivalent system is that formed by two perpendicular linear dipoles with the opposite sign rotated 45° (linear dipole with forces in positive direction corresponds to tension **T** and in negative direction to pressure **P**) for which the elastic displacements are,

$$u_i^{TP} = \int_{-\infty}^{\infty} M(T_k T_k - P_l P_l) G_{ik,jl} d\tau \quad (79)$$

For the two equivalent systems, relations between the unit vectors **P**, **T** and **n**, **l** are $\mathbf{P} = 1/\sqrt{2}(\mathbf{n} - \mathbf{l})$ and $\mathbf{T} = 1/\sqrt{2}(\mathbf{n} + \mathbf{l})$.

7.3 Shear Dislocations

If an earthquake is produced by a fracture of the Earth's crust, a mechanical representation of its source can be given in terms of fractures or dislocations in an elastic medium. The theory of elastic dislocations was developed by Volterra in 1907 and was first applied to the problem of the seismic source in the 1950s by Vvedenskaya, Keylis-Borok, Steketee, Maruyama, and others. A displacement dislocation consists of an internal surface inside an elastic medium across which there exists a discontinuity of displacement but stress is continuous. The focal region consists in an internal surface Σ with two sides (positive and negative). This surface can be considered as derived from a certain focal volume V_0 that is flattened to form a surface with both sides stuck together without any volume. Coordinates on this surface are ξ_k and the normal at each point $n_i(\xi_k)$. From one side to the other of this surface there is a discontinuity in displacement or slip,

$$u_i^+(\xi_k, t) - u_i^-(\xi_k, t) = \Delta u_i(\xi_k, t) \quad (80)$$

where the superscript plus and minus signs refer to the displacement at each side of the surface Σ . If there are no body forces ($\mathbf{F} = 0$), and the stresses are continuous through Σ (their

integral is null) for an infinite medium, Eq. (24) results in

$$u_n(x_s, t) = \int_{-\infty}^{\infty} d\tau \int_{\Sigma} \Delta u_i(\xi_s, \tau) C_{ijkl} n_j(\xi_s) G_{nk,il}(x_s, t; \xi_s, \tau) dS \quad (81)$$

Consequently, the seismic source is represented by a dislocation or discontinuity in displacement given by the slip vector $\Delta \mathbf{u}$ on the surface Σ , which corresponds to the relative displacement between the two sides of a fault. This is, then, a nonelastic displacement that, once produced, does not go back to the initial position. In the most general case, $\Delta \mathbf{u}(\xi_k, \tau)$ can have a different direction for each point ξ_k of the surface Σ and at each of these points varies with time, starting with a zero value at $t = 0$, to a maximum value after a certain time. The normal to the surface Σ , given by unit vector $\mathbf{n}(\xi_k)$, can have different direction at points of the surface, but usually is considered to be constant, that is, Σ is a plane. Green's function **G** includes the propagation effects of the medium from points (ξ_k) of surface Σ to points (x_k) where elastic displacements (u_i) are evaluated. To solve the problem, according to Eq. (81), we must first know the derivatives of Green's function for the medium, which are also known as excitation functions.

Equation (81) corresponds to a kinematic model of the source, that is, a model in which elastic displacements $\mathbf{u}$ are derived from slip vector $\Delta \mathbf{u}$, which represents nonelastic displacement of the two sides of a fault of surface Σ . Slip is assumed to be known and is not derived from stress conditions in the focal region as it is done in dynamic models. In Eq. (81) derivatives of the Green function include derivatives of delta functions. If we change the order of integration, integral on time of the product of $\Delta \mathbf{u}$ with the derivatives of the delta function results in the time derivative of $\Delta \mathbf{u}$, that is, the slip velocity. Thus, elastic displacements depend not on slip but on slip velocity. This means that the source radiates elastic energy only while it is moving; when motion at the source stops, it ceases to radiate energy.

Let us consider the seismic source represented by a shear dislocation fracture, with fault plane Σ of area S and normal $\mathbf{n}$, slip $\Delta \mathbf{u}(\xi_i, t)$ in the direction of unit vector $\mathbf{l}$, contained on the plane so that $\mathbf{l}$ and $\mathbf{n}$ are perpendicular ($\mathbf{n} \cdot \mathbf{l} = 0$). For an infinite, homogeneous isotropic medium, displacement according to Eq. (81) is (Fig. 13),

$$u_k = \int_{-\infty}^{\infty} d\tau \int_{\Sigma} \mu \Delta u (l_i n_j + l_j n_i) G_{ki,jl} dS \quad (82)$$

If the distance from observation point to the source is long in comparison with the source dimensions ($r \gg \Sigma$) and the wavelengths are also long ($\lambda \gg \Sigma$), the problem can be approximated by a point source and Eq. (82) takes the simpler form

$$u_k(t) = \mu S (l_i n_j + l_j n_i) \int_{-\infty}^{\infty} \Delta u(\tau) G_{ki,jl}(t - \tau) d\tau \quad (83)$$

FIGURE 13 Representation of a shear dislocation. (From Udías, 1999.)

Displacements are given by temporal convolution of slip with the derivatives of the Green function. The geometry of the source is now defined by the orientation of the two unit vectors $\mathbf{n}$ and $\mathbf{l}$. These two vectors, referred to the geographical system of axes (North, East, Nadir), define the orientation of the source, namely, $\mathbf{n}$ orientation of the fault plane and $\mathbf{l}$ that of slip.

If we substitute the derivatives of the Green function [Eq. (74)], taking only the terms for the far field, we obtain for the displacements of the P and S waves:

$$u_j^P = \frac{M_0}{4\pi\rho\alpha^3 r} (n_k l_i + n_i l_k) \gamma_i \gamma_k \gamma_j f\left(t - \frac{r}{\alpha}\right) \quad (84)$$

$$u_j^S = \frac{M_0}{4\pi\rho\beta^3 r} (n_k l_i + n_i l_k) (\delta_{ij} - \gamma_i \gamma_j) \gamma_k f\left(t - \frac{r}{\beta}\right) \quad (85)$$

where $M_0 = \mu \Delta \dot{u} S$, is the scalar seismic moment and $f(t)$, the source time function (STF) that represents the time dependence of the slip rate $\Delta \dot{u}$. Therefore, in the far field, P and S waves are pulses that arrive at a distance r at times, $t = r/\alpha$ and $t = r/\beta$, with a form depending on the STF and they are distributed in the space according to the radiation pattern that is a function of n_i , l_i , and γ_i .

8. Seismic Moment Tensor

In the formulation of the theory of source mechanism, an important concept is the seismic moment tensor M_{ij} , and the moment tensor density per unit volume or unit surface m_{ij} :

$$M_{ij} = \int_V m_{ij} dV = \int_S m_{ij} dS \quad (86)$$

The seismic moment tensor was first proposed by Gilbert in 1970, who related it to the total stress drop in earthquakes. Backus and Mulcahy in 1976 showed that the moment tensor represents only that part of the internal stress drop dissipated in nonelastic deformations at the source. The moment tensor is related to the equivalent body forces by

$$F_i = - \frac{\partial m_{ij}}{\partial x_j} \quad (87)$$

The elastic displacements in an infinite medium can now be expressed according to Eq. (76) by a distribution of moment tensor density over the source volume V_0 . In the absence of external forces and torques, the sums of all internal forces and moments are null; then by an appropriate choice of the origin of coordinates, $m_{ij} G_{ij} = 0$, and we obtain

$$u_i = \int_{-\infty}^{\infty} d\tau \int_{V_0} m_{kj} G_{ik,j} dV \quad (88)$$

If the moment tensor is defined only on a surface Σ , we obtain a similar expression in terms of the moment tensor density per unit surface. Equation (88) shows that elastic displacements outside the focal region can be derived from the seismic moment tensor and the derivatives of Green's function integrated over the focal region (V_0 or Σ). Since we have not specified its form, m_{ij} can represent a very general type of source. Each component of m_{ij} is a dipole and, provided the net effect of their sum and the sum of their moments are null, it can correspond to any system of internal body forces. The moment tensor is, thus, a very convenient form to represent the source of an earthquake in a general way. For a point source, Eq. (88) can be written in a compact form using an asterisk to express temporal convolution,

$$u_i = M_{kj} * G_{ik,j} \quad (89)$$

If we compare Eqs. (88) and (81), we can define the moment tensor density corresponding to a dislocation with slip Δu on a surface Σ of normal $\mathbf{n}$:

$$m_{ij} = C_{ijkl} \Delta u_k n_l \quad (90)$$

For an isotropic medium, if the slip direction is given by unit vector $\mathbf{l}$, we obtain

$$m_{ij} = \Delta u [\lambda l_k n_k \delta_{ij} + \mu (l_i n_j + l_j n_i)] \quad (91)$$

In this expression the first term represents changes in volume; if l_k and n_k are perpendicular, this term is zero and the source represents a shear fracture. With the moment tensor we can represent various types of sources. Equation (89) shows that the elastic displacements are linear functions of the components of the moment tensor. Thus, we can obtain these components from observations of displacements by linear inversion.

8.1 Separation of the Moment Tensor

Since the moment tensor is a symmetric tensor, we can obtain its real eigenvalues $\sigma_1, \sigma_2, \sigma_3$ and its eigenvectors $\nu_i^1, \nu_i^2, \nu_i^3$, which are mutually orthogonal and define the principal axes. With respect to these axes, the moment tensor has the form

$$M_{ij} = \begin{pmatrix} \sigma_1 & 0 & 0 \\ 0 & \sigma_2 & 0 \\ 0 & 0 & \sigma_3 \end{pmatrix} \quad (92)$$

In this system, the moment tensor is formed by three linear dipoles in the direction of the principal axes and thus represent the principal stresses. If we order the eigenvalues $\sigma_1 > \sigma_2 > \sigma_3$, then, σ_1 corresponds to the greatest stress, σ_3 to the least stress, and σ_2 to intermediate stress. The sum of the elements of the principal diagonal is the first invariant of the tensor and has the same value for any reference system:

$$M_{11} + M_{22} + M_{33} = \sigma_1 + \sigma_2 + \sigma_3 = 3\sigma_0 \quad (93)$$

This sum represents the change in volume and σ_0 is the isotropic part of the moment tensor. If we subtract this from tensor M_{ij} , we obtain the deviatoric tensor M'_{ij} whose sum of the diagonal elements is always zero and does not include changes in volume,

$$M'_{ij} = M_{ij} - \delta_{ij}\sigma_0 \quad (94)$$

Thus, the moment tensor can be separated into two tensors, one isotropic, $M_{ij}^0 = \delta_{ij}\sigma_0$, representing changes in volume and the other deviatoric M'_{ij} . The moment tensor that represents an explosive source is purely isotropic and that for a shear fracture is purely deviatoric.

Earthquake sources correspond to shear fractures, or nearly so. However, this may not always be the case, so that the presence of changes in volume cannot be completely ruled out. Methods of inversion of the moment tensor from observations that do not impose any condition sometimes result in the presence of certain amounts of isotropic components (changes in volume). More often, the deviatoric part does not correspond exactly to a double-couple source. Then it is convenient to separate the moment tensor into three parts: an isotropic part corresponding to changes in volume, a part of pure shear fracture or double couple (DC), and a third that may represent different mechanisms. This analysis is called partition or separation of the moment tensor and can be expressed by

$$M = M^0 + M^{DC} + M^R \quad (95)$$

In many cases the isotropic part is assumed to be null and is introduced as a condition in the inversion. The deviatoric part is separated into a shear fracture or double-couple source M^{DC} , considered as the standard model for the source of earthquakes, and other effects that are represented by M^R . The partition of the deviatoric part that isolates the double-couple part is not

unique. Usually, a partition is sought for which M^{DC} represents the greatest part of the DC component possible (this is called the best double-couple). A separation that satisfies this condition, introduced by Knopoff and Randall in 1970, is

$$\begin{pmatrix} \sigma_1 & 0 & 0 \\ 0 & \sigma_2 & 0 \\ 0 & 0 & \sigma_3 \end{pmatrix} = \begin{pmatrix} \frac{1}{2}(\sigma_1 - \sigma_3) & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -\frac{1}{2}(\sigma_1 - \sigma_3) \end{pmatrix} + \begin{pmatrix} -\frac{1}{2}\sigma_2 & 0 & 0 \\ 0 & \sigma_2 & 0 \\ 0 & 0 & -\frac{1}{2}\sigma_2 \end{pmatrix} \quad (96)$$

As before, $\sigma_2 = -\sigma_1 - \sigma_3$. The first term is a DC source. The second is called a compensated linear vector dipole (CLVD). Its physical meaning is a sudden change in the shear modulus in a direction normal to the fault plane, without changes in volume. Deviation from a pure DC is sometimes represented by $\delta = |\sigma_3/\sigma_1|$, the ratio of least to greatest eigenvalues. For pure DC, $\delta = 1$ and the non-DC part is given by $1 - \delta$.

9. Models of Fracture

Fracture processes can be approached in two different ways—kinematic and dynamic. Kinematic models of the source consider the slip of the fault without relating it to the stresses that cause it. The fracture process is described purely by the slip vector as a function of coordinates on the fault plane and time. From this type of model, it is a relatively simple problem to determine the corresponding elastic displacement field. Dynamic models consider the complete fracture process relating fault slip to stress acting on the focal region. A complete dynamic description must be able to describe fracture from material properties of the focal region and stress conditions. Dynamic models present greater difficulties and their solutions, in many cases, can only be found by numerical methods.

9.1 Kinematic Models

Let us consider the general characteristics of the kinematic models of extended sources represented by a surface Σ over which a shear dislocation $\Delta u(\xi_i)$ propagates with velocity $v_i(\xi_i)$, from a point ($\xi_i = 0$) to the edge of Σ (Aki and Richards, 1980). In some cases the velocity of fracture propagation is assumed to be constant and less than the velocity of wave propagation ($v < \beta < \alpha$), that is, subsonic fractures (a common value is $v = 0.7\beta$). Displacements of P waves in the far field for an infinite, homogeneous, isotropic medium can be written as

$$u_i^P(x_j, t) = \frac{\mu}{4\pi\rho\alpha^3} \int_{\Sigma} \frac{R(n_k, l_k, \gamma_k)}{r} \Delta \dot{u} \left(\xi_k, t - \frac{r}{\alpha} \right) dS \quad (97)$$

where $r = |x_i - \xi_i|$ is the distance from the point of observation x_i to a point of the source ξ_i , where slip Δu is located at each moment, and $R(n_k, l_k, \gamma_k)$ is the radiation pattern that depends on the orientation of the source (l_k, n_k) and position of the observation point (γ_k).

A simple kinematic model of finite dimensions, known as Haskell's model, is a rectangular fault of length L and width W , where slip Δu propagates only along the L direction with constant velocity v (slip moves instantaneously along W). The coordinate along L is ξ , with origin in one end of the fault, and Δu has only one component (Fig. 14). Fractures that propagate only in one sense (from 0 to L) are called unilateral fractures and those that propagate in both senses (from 0 to $L/2$ and from 0 to $-L/2$) are called bilateral. For unilateral fracture, not considering radiation pattern, dependence on distance, and the other factors of Eq. (97), the form of P waves in the far field, if slip moves in the positive direction of ξ with constant fracture velocity v , $[\Delta u(\xi, t) = \Delta u(t - \xi/v)]$, is given by

$$u(x_i, t) = W \int_0^L \Delta \dot{u} \left[t - \frac{r_0}{\alpha} - \frac{\xi}{\alpha} \left(\frac{\alpha}{v} - \cos \theta \right) \right] d\xi \quad (98)$$

Passing from the domain of time to that of frequency and integrating, the Fourier transform of elastic displacements of P waves $U(x_i, \omega)$, is

$$U(x_i, \omega) = WL\omega \Delta U(\omega) \frac{\sin \omega X}{\omega X} \exp \left[-i \left(\frac{\omega r_0}{\alpha} - \omega X - \frac{\pi}{2} \right) \right] \quad (99)$$

where

$$X = \frac{L}{2\alpha} \left(\frac{\alpha}{v} - \cos \theta \right) \quad (100)$$

The form of the amplitude spectrum depends on the factor $\sin(\omega X)/\omega X$ and the frequency dependence of $\Delta U(\omega)$, the

Fourier transform of the STF. The function $\sin(\omega X)/\omega X$ has a value of unity for $\omega X = 0$, roots for ωX equal to integer multiples of π , and an envelope that decreases as $1/\omega X$. If the STF has a rise time τ , which $\Delta u(t)$ takes to reach its maximum value, then the form of the spectrum has a constant value for low frequencies and for high frequencies starting from a frequency ω_c , called the corner frequency, the envelope of $U(\omega)$ decreases with frequency as $1/\omega^2$ (Fig. 15). Dimensions of the fault are inversely proportional to ω_c .

Another effect of Eq. (99) on the form of the radiation pattern, if wavelengths are of the same order as source dimensions ($\lambda' \sim L$), is that amplitudes are affected by the factor $\sin(\omega X)/\omega X$, which depends on θ . Since this factor is maximum for $\theta = 0$ and minimum for $\theta = \pi$, amplitudes are larger in the same direction as the fracture propagation ($\theta = 0$) and smaller in the opposite direction ($\theta = \pi$). This directivity effect is due to the focusing of energy in the direction of fracture propagation and is a phenomenon present in all propagating sources.

Another fundamental model of an extended seismic source is that of a circular fault, known as Brune's model. This model consists of a circular fault plane with a finite radius (a) on which a shear stress pulse is applied instantaneously. Since this model specifies stress on the fault, this is not exactly a kinematic model. Because the stress pulse is applied instantaneously on the whole fault area, there is no fracture propagation. The form of the spectrum is similar to that of Haskell's model, with corner frequency depending on the radius, $\omega_c = 2.33\beta/a$.

Haskell's model does not include the effect of either the beginning or nucleation of rupture or its stopping or arresting at the fault edge. The first kinematic model that includes both effects was proposed by Savage in 1966. This model consists of an elliptical fault in which slip begins in one of

FIGURE 14 Rectangular fault in Haskell's model. (From Udías, 1999.)

FIGURE 15 Form of the amplitude spectrum of seismic waves from an extended source. (From Udías, 1999.)

the foci and stops when it reaches the border of the ellipse. The result for the elastic displacements is the appearance of a stopping phase when fracture stops at its edge. As rupture propagates outward, motion on the fault stops when it reaches the border of the fault. This way of stopping motion on the fault is not physically possible, since it implies that the information of fault arrest at the edges instantaneously reaches (with infinite velocity) all points of the fault. This can be solved by introducing a finite velocity, for example, velocity of P waves, to bring the information of the cessation of the rupture at the border to all points of the interior of the fault. This wave is called the healing front, since it heals the fault by stopping its motion. In kinematic models, healing of the rupture inside the fault must be introduced in a somewhat artificial way.

9.2 Dynamic Models

Kinematic models are, naturally, a simplification of real fractures and include certain arbitrary properties in the definition of slip and conditions at the fault edge. The physical problem of fracture is a dynamic problem in which slip has to be considered as a result of changes in stress conditions and the strength of material in the focal region. Dynamic models of the seismic source take these conditions into consideration and are based on the theory of fracture generation and propagation in stressed media. Basic notions are presented here; a more detailed discussion of dynamic models is given in Chapter 12 by Madariaga and Olsen, and the physics of the process in Chapter 15 by Teisseyre and Majewski. From the dynamic point of view, the mechanism of an earthquake is represented by a shear fracture produced by the stress drop in the focal region. Fracture begins at a point of the fault when stress acting on the fault plane exceeds a critical value, propagates with a certain velocity, and finally stops when conditions impede its further propagation. A complete dynamic model must, then, include the whole fracture process, its initiation or nucleation, and propagation and arrest, derived from stress conditions and material properties at the focal region. Two determinant factors are tectonic stresses that are the consequence of lithospheric plate motion and mechanical properties of rocks in the fault region.

The dynamic problem of fracture propagation is centered in the energy balance near the rupture front (Kostrov and Das, 1988). For the fracture front to advance, new fracture surface must be created and a certain amount of energy must be consumed. For this, a certain elastic energy flux from the part that has not yet been fractured must reach the fracture front. When the energy flux to the rupture front equals the energy necessary to create new fracture surface or Griffith's energy, then fracture advances. This is called Griffith's fracture condition. For a perfect brittle fracture in elastic material, the material ahead of the fracture front (not yet fractured) is continuous ($u_i^+ = u_i^-$) and that behind (already fractured) is

discontinuous ($u_i^+ - u_i^- = \Delta u_i$). Stress drops by $\Delta\sigma = \sigma_0 - \sigma_f$, where σ_0 is the initial stress and σ_f is the final stress due to friction. There is, then, a discontinuity at the rupture front and there is no transition between unfractured and fractured material.

The relation between stress drop and slip can be stated in a simplified form as follows. We start with the solution of the equation of motion (11) for the relative displacement (slip) of the two sides of the fault plane $\Delta u_i(x_k, t) = u_i^+ - u_i^-$, for $x < vt$, where x is the direction of rupture propagation with velocity v . Boundary conditions require that, as fracture front advances on the fault plane, stress drops by $\Delta\sigma$. If the fracture front is a plane and propagates in the direction of x , with constant velocity v , slip inside the fault can be written as

$$\Delta u(x, t) = \frac{\Delta\sigma}{a} \sqrt{v^2 t^2 - x^2} \quad x < vt \quad (101)$$

and slip velocity as

$$\Delta \dot{u}(x, t) = \frac{V}{\sqrt{v^2 t^2 - x^2}} \quad x < vt \quad (102)$$

If stress drop is total ($\sigma_f = 0$), stress inside the fault is zero and outside,

$$\sigma(x, t) = \frac{K}{\sqrt{x^2 - v^2 t^2}} \quad x > vt \quad (103)$$

where V is the velocity intensity dynamic factor and K is the stress intensity dynamic factor. As the rupture front advances (vt increases in the x direction), slip (101) increases from zero ahead of the rupture front to a constant value inside, slip velocity (102) becomes infinite at the rupture front, and stress (103) becomes infinite when it approaches the rupture front from outside and has either a constant value or zero inside (Fig. 16). Dynamic factors K and V are related to energy flux from unfractured material to the rupture front. For a circular fracture that grows from its center, the relation between Δu and $\Delta\sigma$, known as Kostrov's formula, is

$$\Delta u(r, t) = \frac{\Delta\sigma}{\mu} C(v) v \sqrt{t^2 - \frac{r^2}{v^2}} \quad t > r/v \quad (104)$$

where $v < \beta$, and $C(v)$ is a factor with value near unity. Growth of fracture is assured by constant energy flux from the as yet unfractured material. If the medium is homogeneous, rupture once started cannot stop and grows indefinitely. This is due to the constant conditions of the material ahead of the rupture front.

Since in a homogeneous medium rupture once started cannot stop by itself, stopping must be introduced as a condition; for example, in a circular fault by imposing a limit at a predetermined value of the radius. The beginning of fracture must also be introduced as an added condition; for example,

FIGURE 16 Dependence of slip and slip rate inside the fault and stress outside for total stress drop; $l(t)$ is the position of the rupture front. (From Udías, 1999.)

fracture starts when applied stress exceeds a certain critical value, namely, the maximum stress which the material can support without breaking. Dynamic models of fracture allow determination of slip and its propagation over the fault plane from specified stress drop. Thus, we can find a solution for the elastic displacement field from the dynamic conditions in the source region. The solution of dynamic problems, even for simple cases, is difficult and they must always be solved numerically.

9.3 Complexity of Fracture

Under homogeneous conditions, the dynamic problem of rupture propagation implies certain nonrealistic border conditions concerning stress and slip velocity and nucleation and arrest. To solve some of these problems, we must introduce heterogeneities in the medium and complexities in the fracture process. According to Eqs. (102) and (103) in the homogeneous model, there is a discontinuity of slip velocity and stress at the rupture front that follows from the fact that material is either purely elastic (unfractured) ahead of the front or fractured behind it. To avoid this situation, we must consider the existence of a transition zone immediately ahead of the fracture front where material behaves in a nonelastic form. As introduced by Barenblatt in 1959, this transition zone is called the cohesive zone. In this zone cohesive forces act to oppose the advance of fracture and hold stress finite immediately ahead of the rupture front, eliminating the stress singularity. Slip does not become zero in the cohesive zone and there is no singularity in the slip velocity at the rupture front. In the slip weakening model, cohesive stress is taken to be dependent on slip.

The simple fact that rupture must stop at the edge of the fault indicates that conditions cannot be homogeneous. In the Earth, faults cross rocks of different strength, often change direction, and have jumps, joints, and bends. The analysis of observed wave forms from earthquakes also shows greater

complexity than expected from homogeneous fractures. This is especially present in the complex form of high-frequency waves in the near field and observed values of stress drops, which are really average values over the entire fault zone. Two models have been proposed to explain this complexity, namely, barriers and asperities models.

The barrier model, introduced by Das and Aki in 1977, assumes that fracture takes place under uniform conditions of stress on the fault fracture, but with different strength in the material on the fault surface. Zones with high strength form barriers that make fracture propagation difficult or impede it. Once the fracture process has finished on the whole fault plane, stress is released in fractured zones and accumulated in the unbroken barriers. These can be broken later by aftershocks. The model of asperities, presented by Kanamori in 1978, consists of a fault with a heterogeneous distribution of stress on its surface, with zones of high values (asperities) and low values. This model takes into account the previous history of stress accumulation on certain zones of the fault (asperities) and of stress release on other weaker zones by small earthquakes (foreshocks). Breaking of strong zones or asperities, where high stress has accumulated, constitutes the occurrence of the main large earthquake. In both models, earthquakes are produced by complex fracture processes consisting of the breaking of several asperities or zones between barriers. Since each model cannot explain both foreshocks and aftershocks, mixed models must be considered where both asperities and barriers are present (Kostrov and Das, 1988). Barriers are zones that remain unbroken after the main earthquake and asperities are those that break with high stress drops. Stress distribution on the fault plane is heterogeneous before and after an earthquake.

An important factor in the heterogeneity on the fault surface is the distribution of friction. High and low values of friction along the fault plane contribute to accumulation of stress. Recent dynamic models of fracture give great importance to the problem of friction. The search for more realistic models

of earthquake sources leads to a consideration of complexities in the fracture process, heterogeneities in the distribution of stress, strength, and friction over the fault surface, and the existence of a transition zone at the rupture front. These considerations increase the number of parameters necessary to define source models, introducing dimensions of asperities, distance between barriers, cohesive zone, critical slip, friction distribution, and so on. We must also consider geometric irregularities of the fault surface such as branching, stepping, bending, and junctions that depart from the simple planar model.

10. Conclusions

Theoretical seismology is based on the application of the equations of the mechanics of continuous bodies to the propagation and generation of vibrations produced by earthquakes in the Earth. Basic equations are obtained by assuming perfect elasticity and homogeneous conditions in isotropic material. Heterogeneous conditions in wave propagation and generation require more complex formulations. Anisotropy introduces more than two elastic coefficients and lack of perfect elasticity produces the attenuation of wave amplitudes and normal modes and can be taken into account by means of the quality factor Q . More realistic models of Earth structure and fracture processes require highly heterogeneous three-dimensional models of both source and medium. Solutions for these cases are usually found by means of complex numerical methods.

Seismic Ray Theory and Finite Frequency Extensions

Chris H. Chapman

Schlumberger Cambridge Research, Cambridge, UK

DEDICATION

Franta Hron (University of Alberta) and Carl Spencer (Schlumberger Cambridge Research), both friends and colleagues, died suddenly and prematurely while I was writing this chapter. Franta taught me much about ray theory and Carl about the Kirchhoff integral method. I should like to dedicate this chapter to their memory—I miss you both.

1. Introduction

The application of ray theory to the propagation of elastodynamic waves in the Earth has a long history and an extensive literature. Although ray theory is only a high-frequency approximation, most seismic interpretation relies on it. The classic work of Jeffreys and Bullen, and Gutenberg, in the first half of the 20th century, used ray theory to determine whole Earth structure and locate earthquakes. Ray theory is used to determine crustal structure and dominates interpretation in controlled source seismology, both refraction and reflection. Despite the impressive developments in normal mode and surface wave studies in the last 30 years, ray theory remains the dominant tool for interpretation.

The main advantages of ray theory are that the results, if not the theory, are relatively straightforward and intuitive, and correspond to our everyday experience. Essentially all communications rely on ray theory and the concepts of rays, wavefronts, ray tubes, reflection, and transmission are easily understood. If ray theory were not valid for most seismic signals, our knowledge of the internal structure of the Earth would be much poorer. Ray theory has the added advantage that it is also relatively easy and inexpensive to compute theoretical results.

Despite the fact that historically most seismic studies have treated the Earth as isotropic, in this chapter we have chosen first to develop ray theory in an anisotropic medium. The reason for this is twofold: first, in all branches of seismology there is now considerable interest in and evidence

for anisotropy; and second, anisotropic ray theory is in fact simpler when it is nondegenerate, and it can then be specialized to isotropy. Therefore, in Section 2 we develop anisotropic ray theory. There is a considerable literature on this (for example, Lewis, 1965; Červený, 1972; Hanyga, 1982a; Gajewski and Pšenčík, 1987). The objective of the section is not to introduce anything new, nor to provide a comprehensive review, but to cover all aspects of the theory in a consistent notation and straightforward manner and to obtain the ray theory Green function. The section covers the eikonal and transport equations, kinematic and dynamic raytracing, paraxial rays, interaction with a curved interface, Snell's law, and reflection/transmission coefficients, and finally the ray Green function and its reciprocity. Many alternative but equivalent results have appeared in the literature, but we have made no attempt to review or include all these. Nevertheless, the section should contain sufficient information to compute all parts of the Green function.

Section 3 specializes the results of Section 2, initially to isotropic media and then to 1D or 2D models. In isotropic media, ray theory is degenerate and determining the shear-wave polarization is more complicated. However, other expressions are obviously much simpler in isotropic media. Similarly, simplifying to a 1D medium reduces the ray equations significantly and the standard ray integrals are obtained.

Although ray theory is valid in many circumstances, it breaks down in common situations. Section 4 outlines three useful extensions that remain valid at the singularities of basic ray theory. First, Maslov asymptotic ray theory remains valid at

caustics where rays are focused and the amplitudes of normal ray theory diverge. It also models headwaves on plane interfaces. Only the results of normal raytracing are needed, and the final result is efficiently evaluated in the time-domain as an integral over different ray directions. The result describes the frequency-dependent signals near caustics and diffracted into geometrical shadows. Second, we outline the use of ray theory in the Kirchhoff integral method. This technique models, at least approximately, diffractions from roughness or discontinuities on interfaces. Again, only the results of normal raytracing are needed, to and from the interface, and the final expression is efficiently evaluated in the time-domain as an integral over the interface. The result describes the frequency-dependent, diffracted signals caused by the interface geometry. Finally, we outline quasi-isotropic ray theory. Isotropic and anisotropic ray theories have coexisted and been used for many years in seismology, despite the fact that anisotropic ray theory does not reduce to isotropic theory in the isotropic limit. Since, to a first approximation, the Earth has been treated as isotropic, this fact is surprising and troubling. Normal anisotropic ray theory is only correct when the medium is homogeneous or the anisotropy is strong and we are far from degeneracies. Recently, quasi-isotropic ray theory has been developed, which describes the strong coupling that must exist between shear rays in anisotropic media near degeneracies. Again, using the results of normal raytracing, a simple result is obtained for the frequency-dependent, quasi-shear rays.

2. Asymptotic Ray Theory for 3D, Anisotropic Media

In this section we first develop the basic equations of asymptotic ray theory, the eikonal and transport equations. From these we derive the kinematic and dynamic ray equations, the latter providing solutions for paraxial rays and polarizations. We also solve for the reflection/transmission (r/t) coefficients needed at interfaces in the ray expansion and, combining all these, obtain the ray theory Green function and prove its reciprocity.

The equations for vector/tensor waves can either be written using subscript notation or using vectors, etc. The notation in this chapter is a compromise between these which, at least subjectively, is compact but readable (Woodhouse, 1974; Chapman and Coates, 1994). The operators L , M , and N are close to those in Červený (1972), etc.

The equation of motion is

$$\frac{\partial \mathbf{v}}{\partial t} = \frac{1}{\rho} \frac{\partial \mathbf{t}_j}{\partial x_j} \quad (1)$$

and the constitutive equation for elastic media is

$$\frac{\partial \mathbf{t}_j}{\partial t} = \mathbf{c}_{jk} \frac{\partial \mathbf{v}}{\partial x_k} \quad (2)$$

where $\mathbf{v}$ is the particle velocity, $\mathbf{t}_j$ are the traction vectors (the stress components are $(\mathbf{t}_j)_i = \sigma_{ij}$), $\mathbf{c}_{jk}$ are stiffness matrices (the elastic parameters are $(\mathbf{c}_{jk})_{il} = c_{ijkl}$ and $\mathbf{c}_{jk}^T = \mathbf{c}_{kj}$), and ρ is the density. These equations are the standard equations of motion ($\rho u_{,tt} = \sigma_{ij,j}$) and anisotropic constitutive equation ($\sigma_{ij} = c_{ijkl} u_{k,l}$) (Aki and Richards, 1980, Eqs. (2.17) and (2.18), respectively), rewritten using this vector/matrix notation and to emphasize symmetry. No source term is included as this is not an intrinsic part of ray theory. Later (Section 2.9), we will introduce a general point force to obtain the Green function by matching the ray solution to the known Green function in a homogeneous medium, e.g., Aki and Richards (1980, Ch. 4) for an isotropic medium. More general sources can then be generated by differentiation and superposition (see, for instance, Aki and Richards, 1980, Ch. 4) exploiting the linearity of the wave equations. Eqs. (1) and (2) are easily rewritten in the frequency domain and in this chapter the Fourier transform is defined such that $\partial/\partial t \rightarrow -i\omega$.

2.1 The Ray Expansion

The ray ansätze are

$$\begin{pmatrix} \mathbf{v} \\ \mathbf{t}_j \end{pmatrix}(\omega, \mathbf{x}) = f(\omega) \sum_n e^{i\omega T(\mathbf{x}, \mathcal{L}_n)} \sum_{m=0}^{\infty} \frac{1}{(-i\omega)^m} \begin{pmatrix} \mathbf{V}^{(m)} \\ \mathbf{T}_j^{(m)} \end{pmatrix}(\mathbf{x}, \mathcal{L}_n) \quad (3)$$

where $f(\omega)$ is an arbitrary spectrum depending on the source. The notation $\mathcal{L}_n$ is used to indicate the “ray path”—various paths may exist to the point $\mathbf{x}$ and these are enumerated by the index n . The path in general is a function of the source, receiver, and other parameters along the ray, e.g., the r/t history.

From studies in homogeneous media, it is well known that elastic waves propagate without dispersion with a velocity independent of frequency. At interfaces between homogeneous media, plane waves satisfy Snell’s law. In inhomogeneous media, we expect similar behavior at high frequencies when the wavelength is short compared with the scale of heterogeneities in the medium. The solution is therefore written as a series in *amplitude coefficients*, $\mathbf{V}^{(m)}$ and $\mathbf{T}_j^{(m)}$, which are independent of frequency, and a phase factor linearly dependent on the frequency ω and the *travel time*, T , which again is independent of frequency. At high frequencies, the solution is therefore nondispersive, but the asymptotic series in inverse powers of $-i\omega$ allows for pulse distortion at low frequencies.

Thus the frequency, or time dependence, only enters through the linear phase term and inverse powers in the (asymptotic) expansion. We allow the amplitude coefficients to be complex but require the travel time to be real. Strictly, if the amplitude coefficients are complex, they must depend on the sign of frequency. To obtain a real time series for the solution, we must have $\mathbf{V}^{(m)*}(\omega) = \mathbf{V}^{(m)}(-\omega)$ where $*$ indicates the complex conjugate. Since this is the only frequency

dependence, we omit it from the amplitude coefficients and, where necessary, understand the value for positive frequencies. For generality we have included an arbitrary function of frequency $f(\omega) = f^*(-\omega)$, which in practice will be closely related to the source spectrum.

It is straightforward to write the ansätze of asymptotic ray theory (ART) in the time domain. Inverting the Fourier transform, we obtain

$$\mathbf{V}(\mathbf{x}, t) = \text{Re} \left[F(t) * \sum_n \sum_{m=0}^{\infty} \mathbf{V}^{(m)}(\mathbf{x}, \mathcal{L}_n) \delta^{(m)}(t - T(\mathbf{x}, \mathcal{L}_n)) \right] \quad (4)$$

where $F(t) = f(t) + i\bar{f}(t)$ is the analytic time series corresponding to $f(t)$, and $\delta^{(m)}(t)$ is the m th integral of the Dirac delta function, i.e., $\delta^{(0)}(t) = \delta(t)$ the Dirac delta function, $\delta^{(1)}(t) = H(t)$ the Heaviside function, and $\delta^{(m+1)}(t) = t^m H(t)/m!$ for $m > 1$. In the time domain, it is obvious that the series (4) is not convergent (unless all terms for $m > 1$ are zero, or terms cancel when summed over rays, n). If the series (4) is terminated at $m = M$, then at large times the M th term will dominate and the series will diverge as $t^{M-1}H(t)/(M-1)!$. This is physically impossible (to conserve energy the velocity must decay as $t \rightarrow \infty$). Therefore the series is only asymptotic. Only in special cases, e.g., an isotropic, homogeneous medium, when the series terminates and/or terms cancel in the ray summation, is the series convergent.

Taking the Fourier transformation of Eqs. (1) and (2), substituting Eq. (3) and setting the coefficient of each power of ω to zero, we obtain for $m \geq 0$ (defining $\mathbf{V}^{(-1)} = \mathbf{T}_j^{(-1)} = \mathbf{0}$),

$$\frac{1}{\rho} \frac{\partial \mathbf{T}_j^{(m-1)}}{\partial x_j} = \mathbf{V}^{(m)} + \frac{1}{\rho} p_j \mathbf{T}_j^{(m)} \quad (5)$$

$$\mathbf{c}_{jk} \frac{\partial \mathbf{V}^{(m-1)}}{\partial x_k} = \mathbf{T}_j^{(m)} + p_k \mathbf{c}_{jk} \mathbf{V}^{(m)} \quad (6)$$

where

$$\mathbf{p} = \nabla T \quad (7)$$

is the *slowness vector*, and we have omitted the argument $(\mathbf{x}, \mathcal{L}_n)$. Eliminating $\mathbf{T}_j^{(m)}$ between (5) and (6), we obtain

$$(p_j p_k \mathbf{c}_{jk} - \rho \mathbf{I}) \mathbf{V}^{(m)} = p_j \mathbf{c}_{jk} \frac{\partial \mathbf{V}^{(m-1)}}{\partial x_k} - \frac{\partial \mathbf{T}_j^{(m-1)}}{\partial x_j} \quad (8)$$

which can be solved for the travel time and amplitude coefficients. This equation can be rewritten in shorthand as

$$\mathbf{N}(\mathbf{V}^{(m)}) - \bar{\mathbf{M}}(\mathbf{V}^{(m-1)}, \mathbf{T}_j^{(m-1)}) = \mathbf{0} \quad (9)$$

where

$$\mathbf{N}(\mathbf{V}^{(m)}) = (p_j p_k \mathbf{c}_{jk} - \rho \mathbf{I}) \mathbf{V}^{(m)} \quad (10)$$

$$\bar{\mathbf{M}}(\mathbf{V}^{(m)}, \mathbf{T}_j^{(m)}) = p_j \mathbf{c}_{jk} \frac{\partial \mathbf{V}^{(m)}}{\partial x_k} - \frac{\partial \mathbf{T}_j^{(m)}}{\partial x_j} \quad (11)$$

Substituting for $\mathbf{T}_j^{(m)}$ using Eq. (6), we write

$$\bar{\mathbf{M}}(\mathbf{V}^{(m)}, \mathbf{T}_j^{(m)}) = \mathbf{M}(\mathbf{V}^{(m)}) - \mathbf{L}(\mathbf{V}^{(m-1)}) \quad (12)$$

where

$$\mathbf{M}(\mathbf{V}^{(m)}) = p_j \mathbf{c}_{jk} \frac{\partial \mathbf{V}^{(m)}}{\partial x_k} + \frac{\partial}{\partial x_j} (p_j \mathbf{c}_{jk} \mathbf{V}^{(m)}) \quad (13)$$

$$\mathbf{L}(\mathbf{V}^{(m)}) = \frac{\partial}{\partial x_j} \left(\mathbf{c}_{jk} \frac{\partial \mathbf{V}^{(m)}}{\partial x_k} \right) \quad (14)$$

Note $\bar{\mathbf{M}}(\mathbf{V}^{(0)}, \mathbf{T}_j^{(0)}) = \mathbf{M}(\mathbf{V}^{(0)})$.

2.2 The Eikonal Equation ($m = 0$)

For $m = 0$, Eq. (9) reduces to the eigenvector (Christoffel) equation

$$\frac{1}{\rho} \mathbf{N}(\mathbf{V}^{(0)}) = (p_j p_k \mathbf{c}_{jk} / \rho - \mathbf{I}) \mathbf{V}^{(0)} = \mathbf{0} \quad (15)$$

The 3×3 matrix, $p_j p_k \mathbf{c}_{jk} / \rho$, is real and symmetric, and so has orthogonal eigenvectors (we discuss later how to define these in degenerate cases). We denote the orthonormal eigenvectors as $\hat{\mathbf{g}}_I(\mathbf{x}, \mathbf{p})$, $I = 1, 2$, or 3 , which are defined at all $(\mathbf{x}, \mathbf{p})$. We can define a Hamiltonian

$$H_I(\mathbf{x}, \mathbf{p}) = \frac{1}{2} (p_j p_k \hat{\mathbf{g}}_I^T \mathbf{c}_{jk} \hat{\mathbf{g}}_I / \rho - 1) \quad (16)$$

(with no summation over I). The eigenvalue of $p_j p_k \mathbf{c}_{jk} / \rho$ is unity and eigensolutions of Eq. (15) exist provided

$$|p_j p_k \mathbf{c}_{jk} / \rho - \mathbf{I}| = 0 \quad (17)$$

which is the *eikonal* equation, defining the *slowness surface*. This is equivalent to the constraint

$$H_I(\mathbf{x}, \mathbf{p}) = 0 \quad (18)$$

Substituting Eq. (7) in Eq. (18) shows that the latter is equivalent to the Hamilton–Jacobi equation. Thus the position and slowness must satisfy the Hamilton equations (the *kinematic ray equations*)

$$\frac{dx_i}{dT} = \frac{\partial H}{\partial p_i} = c_{ijkl} p_k \hat{\mathbf{g}}_j \hat{\mathbf{g}}_l / \rho = p_k \hat{\mathbf{g}}_j^T \mathbf{c}_{ik} \hat{\mathbf{g}}_l / \rho = U_i \quad (19)$$

$$\frac{dp_i}{dT} = -\frac{\partial H}{\partial x_i} = -\frac{1}{2} \frac{\partial (c_{jklm} / \rho)}{\partial x_i} p_j p_m \hat{\mathbf{g}}_k \hat{\mathbf{g}}_l \quad (20)$$

(note that derivatives of $\hat{\mathbf{g}}_I(\mathbf{x}, \mathbf{p})$ do not occur in these expressions as for a normalized vector, the derivative is necessarily

FIGURE 1 A ray path and wavefront, and slowness, group, and polarization vectors.

orthogonal). These equations are 6th-order ordinary differential equations that, given initial conditions $\mathbf{x}_0$ and $\mathbf{p}_0$ at $T = T_0$, and a ray type I , can be solved numerically, or occasionally analytically, for the *ray path*, $\mathbf{x}(T)$. This procedure is called *ray shooting*. With the constraint (18), $\mathbf{p}_0$ has only two degrees of freedom, i.e., to define its direction. Later we parametrize this direction with ray parameters q_1 and q_2 . Equation (19) defines the *ray or group velocity*

$$\frac{d\mathbf{x}}{dT} = \mathbf{U} \quad (21)$$

The useful relationship

$$\mathbf{p} \cdot \mathbf{U} = 1 \quad (22)$$

can be obtained from the geometry of the wavefront (the slowness vector $\mathbf{p} = \nabla T$ is normal to the wavefront, while Eq. (22) holds whatever the ray direction, $\mathbf{U}$). It can also be obtained algebraically from Eq. (19) using the constraint (18). Figure 1 illustrates a ray path found by solving the kinematic ray equations, a wavefront defined by constant travel time, T , and the slowness, group, and polarization vectors, $\mathbf{p}$, $\mathbf{U}$, and $\hat{\mathbf{g}}$, respectively.

2.3 The Transport Equation ($m \geq 1$)

First we consider the general transport equation and then specialize to find the zeroth-order amplitude coefficients. The equations are solved iteratively so we assume we have solved for the amplitude coefficients to order $m - 1$, and are solving for order m .

Let us write $\mathbf{V}^{(m)}$ in terms of the orthogonal eigenvectors

$$\mathbf{V}^{(m)} = V_i^{(m)} \hat{\mathbf{g}}_i \quad (23)$$

Premultiplying Eq. (9) by $\hat{\mathbf{g}}_I^T$ and substituting Eq. (23), we obtain

$$\begin{aligned} \hat{\mathbf{g}}_I^T \bar{\mathbf{M}}(\mathbf{V}^{(m-1)}, \mathbf{T}_j^{(m-1)}) &= \hat{\mathbf{g}}_I^T \mathbf{N}(\mathbf{V}^{(m)}) \\ &= \hat{\mathbf{g}}_I^T (p_i p_k \mathbf{c}_{jk} - \rho \mathbf{I}) V_i^{(m)} \hat{\mathbf{g}}_i \\ &= 2\rho V_I^{(m)} H_I \end{aligned} \quad (24)$$

(no summation over I) using the orthogonality of the eigenvectors, $\hat{\mathbf{g}}_i$, of the matrix $p_i p_k \mathbf{c}_{jk}$.

In general H_I will be zero when I corresponds to the ray type, and nonzero for the other indices. In degenerate cases, $H_I = 0$ for two indices. We denote indices for which $H_I = 0$ by $I = E$, and $H_I \neq 0$ by $I = N$ (summation over an upper-case index is restricted to one or two terms. For instance, E might be the index 2 and N the set of indices 1 and 3. In a degenerate case, E might be the set 1 and 2, and N just 3).

We can solve Eq. (24) for the $V_N^{(m)}$, i.e.,

$$V_N^{(m)} = \frac{1}{2\rho H_N} \hat{\mathbf{g}}_N^T \bar{\mathbf{M}}(\mathbf{V}^{(m-1)}, \mathbf{T}_j^{(m-1)}) \quad (25)$$

(no summation over N). These components are called the *additional terms* and we write them as

$$\mathbf{W}^{(m)} = V_N^{(m)} \hat{\mathbf{g}}_N \quad (26)$$

(summation over N). They can be found from the known, lower-order terms (25). Thus Eq. (23) is

$$\mathbf{V}^{(m)} = V_E^{(m)} \hat{\mathbf{g}}_E + \mathbf{W}^{(m)} \quad (27)$$

$V_E^{(m)}$ are called the *principal component(s)*.

First let us consider the nondegenerate case, where there is only one E index. Later we show how, with the correct choice of eigenvectors, the same method can be used to find the principal components in the degenerate case (where there are two E indices).

Setting $I = E$ and $m - 1 \rightarrow m$ in Eq. (24), we have (since $H_E = 0$)

$$\hat{\mathbf{g}}_E^T \bar{\mathbf{M}}(\mathbf{V}^{(m)}, \mathbf{T}_j^{(m)}) = 0$$

Separating the part that is known using Eqs. (12) and (27), we obtain

$$\hat{\mathbf{g}}_E^T \mathbf{M}(V_E^{(m)} \hat{\mathbf{g}}_E) = \hat{\mathbf{g}}_E^T \left(\mathbf{L}(\mathbf{V}^{(m-1)}) - \mathbf{M}(\mathbf{W}^{(m)}) \right) = \xi^{(m)} \quad (28)$$

say. The RHS, $\xi^{(m)}$, can, at least in principle, be calculated from the known terms, $\mathbf{V}^{(m-1)}$ and $\mathbf{W}^{(m)}$. Overall, this equation is a scalar and so we can transpose the second term in $\mathbf{M}$, and multiply by $V_E^{(m)}$ to reduce it, using Eq. (19), to a simple differential:

$$\nabla \cdot (\rho V_E^{(m)2} \mathbf{U}) = V_E^{(m)} \xi^{(m)} \quad (29)$$

This can be rewritten

$$\frac{d}{dT} \ln(\rho V_E^{(m)2}) = \frac{\xi^{(m)}}{\rho V_E^{(m)}} - \nabla \cdot \mathbf{U} \quad (30)$$

using $\mathbf{U} \cdot \nabla = d/dT$. This [Eq. (30)], or variants thereof, is known as the *transport equation*.

FIGURE 2 A ray tube formed by perturbations dq_1 and dq_2 .

Suppose the ray paths are $\mathbf{x} = \mathbf{x}(T, q_1, q_2)$, where, q_1 and q_2 are two parameters describing the initial conditions. Smirnov's lemma (Thomson and Chapman, 1985) gives that if Eq. (21) holds, then

$$\frac{d}{dT} \left(\ln \frac{\partial(x_1, x_2, x_3)}{\partial(T, q_1, q_2)} \right) = \nabla \cdot \mathbf{U}$$

The Jacobian is derived considering differentials of the ray with respect to the initial conditions. A ray tube is defined by perturbations dq_1 and dq_2 to the ray parameters. Figure 2 illustrates a ray tube formed by perturbations dq_1 and dq_2 . The cross-section of the ray tube in the wavefront is defined as $J dq_1 dq_2$. The Jacobian is therefore

$$\frac{\partial(x_1, x_2, x_3)}{\partial(T, q_1, q_2)} = \frac{d\mathbf{x}}{dT} \cdot \left(\frac{\partial\mathbf{x}}{\partial q_1} \times \frac{\partial\mathbf{x}}{\partial q_2} \right) = UJ \cos \phi = uJ \quad (31)$$

where u is the phase velocity ($u|\mathbf{p}| = 1$), U is the group velocity ($U = |\mathbf{U}|$), and ϕ is the angle between the slowness vector, $\mathbf{p}$, and the ray velocity, $\mathbf{U}$ [Eq. (22) gives $U \cos \phi = u$]. Thus

$$\frac{d}{dT} \ln(uJ) = \nabla \cdot \mathbf{U} \quad (32)$$

Combining Eqs. (30) and (32), we obtain

$$\frac{d}{dT} \ln(\rho u V_E^{(m)2} J) = \frac{\xi^{(m)}}{\rho V_E^{(m)}}$$

or

$$\frac{d}{dT} \left(V_E^{(m)} \sqrt{\rho u |J|} \right) = \frac{1}{2} \sqrt{\frac{u |J|}{\rho}} \xi^{(m)} \quad (33)$$

This is simply solved as

$$V_E^{(m)} = \frac{1}{\sqrt{\rho u |J|}} \left(\text{constant} + \frac{1}{2} \int_{\mathcal{L}_n} \sqrt{\frac{u |J|}{\rho}} \xi^{(m)} dT \right) \quad (34)$$

It is now trivial to specialize these results to the zeroth-order coefficients. With $m=0$, the additional terms (25) are zero and $\mathbf{W}^{(0)} = \mathbf{0}$. Thus the polarization of the leading term in

the ray expansion (3) is parallel to the corresponding eigenvector, $\hat{\mathbf{g}}_E$. For the principal component, $\xi^{(0)} = 0$ and Eq. (34) reduces to

$$V_E^{(0)} = \frac{\text{constant}}{\sqrt{\rho u |J|}} \quad (35)$$

The zeroth-order transport equation (29) can be written

$$\nabla \cdot \mathbf{N} = 0 \quad \text{where} \quad N_j = -\mathbf{V}^{(0)\text{T}} \mathbf{T}_j^{(0)} = \rho V^{(0)2} U_j \quad (36)$$

and $\mathbf{N}$ is the *energy flux vector* (cf. the Poynting vector in electromagnetism). The amplitude coefficients may be complex due to caustics or total reflections, etc. Eq. (36) does not hold at caustics or r/t points.

2.4 Paraxial Ray Equations

In this section we derive the equations needed to obtain the amplitude coefficient, in particular the function J . The *dynamic ray equations* are obtained by perturbing the ray position and slowness in the kinematic ray equations (19) and (20). This can be written

$$\frac{d\mathbf{y}}{dT} = \begin{pmatrix} \mathbf{T}^{\text{T}} & \mathbf{R} \\ \mathbf{S} & -\mathbf{T} \end{pmatrix} \mathbf{y} = \mathbf{D}\mathbf{y} \quad (37)$$

say, where $\mathbf{y} = (\delta\mathbf{x} \ \delta\mathbf{p})^{\text{T}}$ is the 6-vector perturbation of the ray position and slowness, and $T_{ij} = \partial^2 H / \partial x_i \partial p_j$, $R_{ij} = \partial^2 H / \partial p_i \partial p_j$ and $S_{ij} = \partial^2 H / \partial x_i \partial x_j$. In principle, this 6th-order system has six solutions, but only four of them are of interest: perturbations in the ray direction at the source; and perturbations of the source position perpendicular to the slowness direction at the source. Another solution, the perturbation along the ray, can be obtained directly from the kinematic ray results, and the slowness constraint (18) eliminates the other. However, first let us consider the complete 6th-order system.

The dynamic equations (37) have symplectic symmetry, which can be used to prove the reciprocity of the ray results and provides a useful check on numerical solutions. It is convenient to define

$$\mathbf{I}_1 = \begin{pmatrix} \mathbf{0} & \mathbf{I} \\ -\mathbf{I} & \mathbf{0} \end{pmatrix}, \quad \mathbf{I}_2 = \begin{pmatrix} \mathbf{0} & \mathbf{I} \\ \mathbf{I} & \mathbf{0} \end{pmatrix} \quad \text{and} \quad \mathbf{I}_3 = \begin{pmatrix} -\mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{I} \end{pmatrix} \quad (38)$$

Because $\mathbf{R}$ and $\mathbf{S}$ are symmetric, it is easily shown that

$$\mathbf{D} = \mathbf{I}_1 \mathbf{D}^{\text{T}} \mathbf{I}_1 = -\mathbf{D}^{\dagger} \quad (39)$$

say. We call this a *symplectic symmetry* (and $\mathbf{D}^{\dagger}$ a *symplectic transform*).

Consider a propagator solution of Eq. (37) from T_0 to T , i.e., $\mathbf{P}(T, T_0)$, which satisfies Eq. (37) and $\mathbf{P}(T_0, T_0) = \mathbf{I}$. Expanding the derivative of $\mathbf{P}^{\text{T}} \mathbf{I}_1 \mathbf{P}$ and using Eq. (37), its transpose,

$\mathbf{I}_1^2 = -\mathbf{I}$, and Eq. (39), we obtain

$$\frac{d}{dT}(\mathbf{P}^T \mathbf{I}_1 \mathbf{P}) = 0, \quad \text{i.e.,} \quad \mathbf{P}^T \mathbf{I}_1 \mathbf{P} = \mathbf{I}_1 \quad (40)$$

from the value at T_0 . Multiplying by $-\mathbf{I}_1$, this establishes that

$$\mathbf{P}^{-1}(T, T_0) = -\mathbf{I}_1 \mathbf{P}(T, T_0) \mathbf{I}_1 = \mathbf{P}^\dagger(T, T_0) = \begin{pmatrix} \mathbf{P}_{pp}^T & -\mathbf{P}_{xp}^T \\ -\mathbf{P}_{px}^T & \mathbf{P}_{xx}^T \end{pmatrix} \quad (41)$$

where $\mathbf{P}$ has been written as 3×3 submatrices

$$\mathbf{P} = \begin{pmatrix} \mathbf{P}_{xx} & \mathbf{P}_{xp} \\ \mathbf{P}_{px} & \mathbf{P}_{pp} \end{pmatrix} \quad (42)$$

Thus the inverse propagator, or the propagator in the reverse direction, $\mathbf{P}(T_0, T) = \mathbf{P}^{-1}(T, T_0)$, can be obtained by symplectic transformation, which is significantly easier than inverting a 6×6 matrix. The particular result we will need is

$$\mathbf{P}_{xp}(T_0, T) = -\mathbf{P}_{xp}^T(T, T_0) \quad (43)$$

2.5 Rays at an Interface

The above results describe rays in media without discontinuities. If the medium contains interfaces, i.e., discontinuities in the material properties ρ or $\mathbf{c}_{jk}$, then the ray theory solution breaks down due to discontinuities in the solution or its derivatives. It is necessary to impose the discontinuities on the solution at the interface before continuing the ray solution, and this is investigated in this section.

Let us define the interface separating two different media by $S(\mathbf{x})=0$. For simplicity, let us label these media 1 and 2, where the wave is incident from medium 1. A normal to the interface is defined by $\hat{\mathbf{n}} = \epsilon \nabla S$ where $\epsilon = \pm |\nabla S|^{-1}$ and by convention the sign is taken so the vector $\hat{\mathbf{n}}$ points into medium 1. In order to solve the continuity conditions at the interface, it is convenient to transform the elastic parameters into an interface coordinate system, where the direction $\hat{\mathbf{n}}$ is an axis. We complete an orthogonal basis at the point where the ray intersects the interface by defining two vectors, $\hat{\mathbf{l}}$ and $\hat{\mathbf{m}}$, in the tangent plane of the interface. The orientation of these is arbitrary but in an isotropic medium it is convenient to choose one in the plane of the ray and the normal, and one normal to this ray plane, i.e.,

$$\hat{\mathbf{m}} = \frac{\hat{\mathbf{n}} \times \mathbf{U}}{|\hat{\mathbf{n}} \times \mathbf{U}|} \quad \text{and} \quad \hat{\mathbf{l}} = \hat{\mathbf{m}} \times \hat{\mathbf{n}} \quad (44)$$

in order to separate the SV and SH components of the shear wave. In anisotropic media, we might as well use the same basis. When Eq. (44) degenerates (when the ray is normal

to the interface), any choice will do. Defining an orthonormal transformation matrix $\mathbf{L} = (\hat{\mathbf{l}} \hat{\mathbf{m}} \hat{\mathbf{n}})$, we can transform any vector/tensor components to the interface basis, e.g.,

$$c'_{ijkl} = L_{i'i} L_{j'j} L_{k'k} L_{l'l} c_{ijkl} \quad (45)$$

where the prime indicates values in this interface basis.

Assuming the interface is welded, the boundary condition is that the particle velocity, $\mathbf{v}$, and the interface traction, $\mathbf{t}_n = \mathbf{t}'_3 = \hat{\mathbf{n}}_j \mathbf{t}_{ij}$, should be continuous. For later use, we define a 6-vector of the amplitude coefficients of these continuous field variables,

$$\mathbf{w} = \begin{pmatrix} \mathbf{V}^{(0)} \\ \mathbf{T}_n^{(0)} \end{pmatrix} = \begin{pmatrix} \mathbf{V}^{(0)} \\ \mathbf{T}_3^{(0)'} \end{pmatrix} \quad (46)$$

In general, continuity of $\mathbf{w}$ is impossible for just one ray incident and one ray leaving the interface. The continuity of the six components of $\mathbf{w}$ require that six new rays be generated by one incident ray: Three rays radiated away from the interface in each medium, *reflected* in medium 1, and *transmitted* in medium 2. The six continuity conditions determine the amplitudes of the six generated rays. We denote any property of these rays by two subscripts, e.g., $\mathbf{p}_{kl}$ are the slowness vectors with $k=1$ or 2 indicating the medium, and $l=1, 2$ or 3, the ray type. The ordering of the ray types is not crucial but it is convenient to use $l=1$ to indicate the slower qS wave, 2 the faster qS wave, and 3 the qP wave (i.e., in order of increasing velocity). We indicate the incident wave with a single, ray-type subscript j , i.e., $\mathbf{p}_j$. All rays will intersect the interface at the same point, $\mathbf{x} = \mathbf{x}_j = \mathbf{x}_{kl}$. In general, the existence of all six generated rays is necessary to satisfy the continuity of $\mathbf{w}$, but, having solved for the starting conditions of the generated rays, in practice we follow each generated ray separately. A complete ray consists of a sequence of *ray segments* between interfaces, and the *ray history* or *signature* describes the sequence of choices defining the generated ray type at each interface. The incident and generated ray choice at an interface is indicated by the *coefficient triplet* $\{j, k, l\}$. The complete response consists of a sum of rays with all possible histories—this is enumerated by the index n in Eq. (3).

Throughout the rest of this section, we assume variables are in the interface basis, e.g., (45), and for brevity we omit the prime.

2.6 Kinematic Continuity—Snell's Law

Continuity of $\mathbf{w}$ at an interface requires that T and its gradient in the plane of the interface are the same for all rays. Continuity of T is trivial, just imposing an initial condition on the new ray segment. Continuity of the gradient of T [Eq. (7)] in the plane of the interface leads to the slowness vectors for the generated rays and the initial conditions for the kinematic ray equations of the generated ray.

The slowness in the plane of the interface is given by

$$\mathbf{p}_\perp = \mathbf{p} - (\mathbf{p} \cdot \hat{\mathbf{n}})\hat{\mathbf{n}} = p_1 \hat{\mathbf{l}} + p_2 \hat{\mathbf{m}} \quad (47)$$

This must be the same for all the rays at the interface and can be calculated for the incident ray. Thus the generated rays will have slownesses

$$\mathbf{p}_{kl} = p_n \hat{\mathbf{n}} + \mathbf{p}_\perp = p_3 \hat{\mathbf{n}} + \mathbf{p}_j - (\mathbf{p}_j \cdot \hat{\mathbf{n}})\hat{\mathbf{n}} \quad (48)$$

where p_3 must be found from the constraint (18), i.e.,

$$H_{kl}(\mathbf{x}, \mathbf{p}_{kl}) = 0 \quad (49)$$

is solved for p_3 (below in Eq. (67), we give a 6th-order eigen-equation for $\mathbf{w}$ that can be solved for the eigenvalue p_3). In general, there will be six solutions for p_3 and we must choose the solutions corresponding to the waves propagating away from the interface. From the $\mathbf{p}_{kl}$, we derive the ray velocities $\mathbf{U}_{kl}$ using Eq. (19) and choose the correct solutions using the constraints

$$\hat{\mathbf{n}} \cdot \mathbf{U}_{1l} > 0 \quad \text{and} \quad \hat{\mathbf{n}} \cdot \mathbf{U}_{2l} < 0 \quad (50)$$

which follow from the convention used to define the sign of $\hat{\mathbf{n}}$ ($\hat{\mathbf{n}} \cdot \mathbf{U}_j < 0$, necessarily). They can be ordered in l using the velocity criteria suggested above. Note that the ray velocity, $\mathbf{U}_{kl}$, rather than the slowness, $\mathbf{p}_{kl}$, should be used in these conditions (50)—in some situations in anisotropic media, the two conditions differ (Garmany, 1988).

In some circumstances, some of the solutions for p_3 may be complex, i.e., the waves may be evanescent. While these waves should be included to solve for the amplitude continuity condition, the corresponding rays are not normally included in the ray solution.

The relationship between the slowness vectors, $\mathbf{p}_j$ and $\mathbf{p}_{kl}$, is known as *Snell's law*. This and the continuity of $\mathbf{x}$ and T give the required conditions for kinematic raytracing through an interface.

2.7 Paraxial Ray Discontinuity

In order to continue the solution of the dynamic ray equations (37) through an interface, we must connect the derivatives of $\mathbf{x}$, $\mathbf{p}_j$, and $\mathbf{p}_{kl}$ (see Figure 3). Results have been given by Červený *et al.* (1974) (for isotropic media) and Gajewski and Pšenčík (1990) (for anisotropic media). These have been modified by Farra and Le Bégat (1995) to maintain the symplectic symmetries (41) and in this section we summarize their results.

In order to study the derivatives, it is crucial to distinguish the values in the wavefront (as given by the dynamic ray equations (37) with constant T), and those on the interface ($S=0$). These are related by

$$\left. \frac{\partial}{\partial q_\nu} \begin{pmatrix} \mathbf{x} \\ \mathbf{p} \end{pmatrix} \right|_S = \left. \frac{\partial}{\partial q_\nu} \begin{pmatrix} \mathbf{x} \\ \mathbf{p} \end{pmatrix} \right|_T + \left. \frac{\partial T}{\partial q_\nu} \right|_S \begin{pmatrix} \dot{\mathbf{x}} \\ \dot{\mathbf{p}} \end{pmatrix} \quad (51)$$

FIGURE 3 A ray and a paraxial ray at an interface, showing the connection between wavefront and interface perturbations, i.e., Eq. (51).

where for brevity we have written $d\mathbf{x}/dT = \dot{\mathbf{x}}$, etc., given by Eqs. (19) and (20) (Greek subscripts, e.g., ν , are restricted to 1 and 2). The position derivative $\partial \mathbf{x} / \partial q_\nu|_S$ must be in the interface, so premultiplying by $\hat{\mathbf{n}}^T$, we can solve for the travel time interface derivative

$$\left. \frac{\partial T}{\partial q_\nu} \right|_S = - \left. \frac{\hat{\mathbf{n}}^T}{\dot{\mathbf{x}}_j^T \hat{\mathbf{n}}} \frac{\partial \mathbf{x}}{\partial q_\nu} \right|_T \quad (52)$$

Substituting in Eq. (51) we can convert the wavefront perturbation to the interface

$$\mathbf{y}_j|_S = \begin{pmatrix} \mathbf{F}_1 & \mathbf{0} \\ \mathbf{F}_2 & \mathbf{I} \end{pmatrix} \mathbf{y}_j|_T \quad (53)$$

where

$$\mathbf{F}_1 = \mathbf{I} - \frac{\dot{\mathbf{x}}_j \hat{\mathbf{n}}^T}{\dot{\mathbf{x}}_j^T \hat{\mathbf{n}}} \quad \text{and} \quad \mathbf{F}_2 = - \frac{\dot{\mathbf{p}}_j \hat{\mathbf{n}}^T}{\dot{\mathbf{x}}_j^T \hat{\mathbf{n}}} \quad (54)$$

The position of the incident ray on the interface and the generated ray are identical, i.e.,

$$\mathbf{x}_j|_S = \mathbf{x}_{kl}|_S \quad (55)$$

so perturbations are also equal. A useful expression can be obtained using Eq. (51) in the expression for the ray-tube cross-section [Eq. (31) with $\dot{\mathbf{x}} = \mathbf{U}$ (19)]:

$$\frac{u_j J_j}{\mathbf{U}_j^T \hat{\mathbf{n}}} = \frac{u_{kl} J_{kl}}{\mathbf{U}_{kl}^T \hat{\mathbf{n}}} \quad (56)$$

However, the connection between the slowness vectors is more complicated. The difference between the generated and incident slownesses is normal to the interface [Eq. (48)], i.e.,

$$\mathbf{p}_{kl} - \mathbf{p}_j = \hat{\mathbf{n}}^T (\mathbf{p}_{kl} - \mathbf{p}_j) \hat{\mathbf{n}} \quad (57)$$

This can be differentiated with respect to q_ν . To evaluate the differentials of the RHS, we use the differentials of the Hamiltonians

$$\frac{\partial H}{\partial q_\nu} = -\dot{\mathbf{p}}^T \frac{\partial \mathbf{x}}{\partial q_\nu} \Big|_S + \dot{\mathbf{x}}^T \frac{\partial \mathbf{p}}{\partial q_\nu} \Big|_S = 0 \quad (58)$$

for either the incident ray, H_j , or generated ray, H_{kl} , with Eqs. (19) and (20). Premultiplying the differential of Eq. (57) by $\dot{\mathbf{x}}_{kl}^T$ and using Eq. (58) for H_{kl} , we can solve for $\partial[\hat{\mathbf{n}}^T(\mathbf{p}_{kl} - \mathbf{p}_j)]/\partial \mathbf{q}_\nu|_S$. With

$$\left. \frac{\partial \hat{\mathbf{n}}}{\partial \mathbf{q}_\nu} \right|_S = \nabla^T \hat{\mathbf{n}} \left. \frac{\partial \mathbf{x}}{\partial \mathbf{q}_\nu} \right|_S \quad (59)$$

the differentials of Eqs. (57) and (55) can be written

$$\mathbf{y}_{kl}|_S = \begin{pmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{F}_3 & \mathbf{F}_4 \end{pmatrix} \mathbf{y}_j|_S \quad (60)$$

where

$$\mathbf{F}_3 = \frac{\hat{\mathbf{n}}}{\dot{\mathbf{x}}_{kl}^T \hat{\mathbf{n}}} (\dot{\mathbf{p}}_{kl} - \dot{\mathbf{p}}_j)^T + \hat{\mathbf{n}}^T (\mathbf{p}_{kl} - \mathbf{p}_j) \left(\mathbf{I} - \frac{\hat{\mathbf{n}} \dot{\mathbf{x}}_{kl}^T}{\dot{\mathbf{x}}_{kl}^T \hat{\mathbf{n}}} \right) \nabla^T \hat{\mathbf{n}} \quad (61)$$

$$\mathbf{F}_4 = \mathbf{I} - \frac{\hat{\mathbf{n}} (\dot{\mathbf{x}}_{kl} - \dot{\mathbf{x}}_j)^T}{\dot{\mathbf{x}}_{kl}^T \hat{\mathbf{n}}} \quad (62)$$

Note that these matrices contain factors that combine to give Eq. (58) for H_j , i.e., zero in the perturbation, but are included in the propagator (60) so it satisfies the symplectic symmetry (41) (Farra and Le Bégat, 1995). Finally, we use Eqs. (51) and (52) to convert the perturbation (60) onto the wavefront, i.e.,

$$\mathbf{y}_{kl}|_T = \mathbf{y}_{kl}|_S + \begin{pmatrix} \mathbf{F}_5 & \mathbf{0} \\ \mathbf{F}_6 & \mathbf{0} \end{pmatrix} \mathbf{y}_j|_T \quad (63)$$

where

$$\mathbf{F}_5 = \frac{\dot{\mathbf{x}}_{kl} \hat{\mathbf{n}}^T}{\dot{\mathbf{x}}_j^T \hat{\mathbf{n}}} \quad \text{and} \quad \mathbf{F}_6 = \frac{\dot{\mathbf{p}}_{kl} \hat{\mathbf{n}}^T}{\dot{\mathbf{x}}_j^T \hat{\mathbf{n}}} \quad (64)$$

Overall

$$\mathbf{y}_{kl}|_T = \mathbf{F} \mathbf{y}_j|_T \quad (65)$$

where

$$\mathbf{F} = \begin{pmatrix} \mathbf{F}_1 + \mathbf{F}_5 & \mathbf{0} \\ \mathbf{F}_3 \mathbf{F}_1 + \mathbf{F}_4 \mathbf{F}_2 + \mathbf{F}_6 & \mathbf{F}_4 \end{pmatrix} \quad (66)$$

propagates the perturbation from the incident to the generated ray. It satisfies the symplectic symmetry (41) (Farra and Le Bégat, 1995).

2.8 Reflection/Transmission Coefficients

At an interface, the 6-vector $\mathbf{w}$ [Eq. (46)] is continuous. We can use this condition to calculate the magnitudes of the generated rays relative to the incident ray, i.e., the *reflection/transmission coefficients*. Eliminating the discontinuous $\mathbf{T}_\nu^{(0)}$'s from Eqs. (5) and (6), we obtain

$$\mathbf{A} \mathbf{w} = p_3 \mathbf{w} \quad (67)$$

where

$$\mathbf{A}_{22} = \mathbf{A}_{11}^T = -p_\eta \mathbf{c}_{\eta 3} \mathbf{c}_{33}^{-1} \quad (68)$$

$$\mathbf{A}_{12} = -\mathbf{c}_{33}^{-1} \quad (69)$$

$$\mathbf{A}_{21} = p_\eta p_\nu \mathbf{c}_{\eta \nu} - \rho \mathbf{I} - p_\eta p_\nu \mathbf{c}_{\eta 3} \mathbf{c}_{33}^{-1} \mathbf{c}_{3 \nu} \quad (70)$$

This eigenequation (67) can be solved for six eigenvalues p_3 . Let us write the eigensolutions as

$$\mathbf{A} \mathbf{W} = \mathbf{W} \mathbf{p}_3 \quad (71)$$

where the columns of $\mathbf{W}$ are the eigenvectors $\mathbf{w}$, and $\mathbf{p}_3$ is the diagonal matrix of eigenvalues. We order the eigenvectors so the first three correspond to waves propagating in the positive $\hat{\mathbf{n}}$ direction, i.e., $\hat{\mathbf{n}} \cdot \mathbf{U} > 0$, and the last three are traveling in the opposite direction, i.e., $\hat{\mathbf{n}} \cdot \mathbf{U} < 0$. Within the triplets, we order them with increasing velocity as suggested above. In general, some of the eigenvalues for the generated waves may be complex, corresponding to evanescent waves. The eigenvectors should be ordered according to their evanescent decay.

The various r/t experiments can be described by a matrix equation,

$$\mathbf{W}_1 \begin{pmatrix} \mathcal{T}_{11} & \mathcal{T}_{12} \\ \mathbf{I} & \mathbf{0} \end{pmatrix} = \mathbf{W}_2 \begin{pmatrix} \mathbf{0} & \mathbf{I} \\ \mathcal{T}_{21} & \mathcal{T}_{22} \end{pmatrix} \quad (72)$$

where $\mathbf{W}_1$ and $\mathbf{W}_2$ are the eigenvectors in the two media, $\mathcal{T}$ is a 6×6 matrix of r/t coefficients, and the 3×3 submatrices in Eq. (72), $\mathcal{T}_{ki}$, are the coefficients where the incident waves' medium is indicated by i , and the generated waves' medium is indicated by k (the unit matrices $\mathbf{I}$ represent the incident waves). The elements of the full matrices and submatrices are related by

$$(\mathcal{T}_{ki})_{lj} = \mathcal{T}_{l+3(k-1)j+3(i-1)} \quad (73)$$

where j (column index) and l (row index) indicate the incident and generated wave types, respectively (the symbols correspond to the coefficient triplet $\{j, k, l\}$ used in Sections 2.5, 2.6, and 2.7, with $i = 1$ by design). Figure 4 illustrates the r/t experiments represented by Eq. (72). Solving this equation we have

$$\begin{aligned} & \begin{pmatrix} \mathcal{T}_{11} & \mathcal{T}_{12} \\ \mathbf{I} & \mathbf{0} \end{pmatrix} \begin{pmatrix} \mathbf{0} & \mathbf{I} \\ \mathcal{T}_{21} & \mathcal{T}_{22} \end{pmatrix}^{-1} \\ &= \begin{pmatrix} \mathcal{T}_{12} - \mathcal{T}_{11} \mathcal{T}_{21}^{-1} \mathcal{T}_{22} & \mathcal{T}_{11} \mathcal{T}_{21}^{-1} \\ -\mathcal{T}_{21}^{-1} \mathcal{T}_{22} & \mathcal{T}_{21}^{-1} \end{pmatrix} = \mathbf{W}_1^{-1} \mathbf{W}_2 \\ &= \mathbf{Q} \end{aligned} \quad (74)$$

FIGURE 4 Reflection/transmission experiments—each represents three incident ray types and six generated rays (36 r/t coefficients in total).

say. This can be solved for the coefficient matrix

$$\begin{aligned} \mathcal{T} &= \begin{pmatrix} \mathcal{T}_{11} & \mathcal{T}_{12} \\ \mathcal{T}_{21} & \mathcal{T}_{22} \end{pmatrix} \\ &= \begin{pmatrix} \mathbf{Q}_{12}\mathbf{Q}_{22}^{-1} & \mathbf{Q}_{11} - \mathbf{Q}_{12}\mathbf{Q}_{22}^{-1}\mathbf{Q}_{21} \\ \mathbf{Q}_{22}^{-1} & -\mathbf{Q}_{22}^{-1}\mathbf{Q}_{21} \end{pmatrix} \end{aligned} \quad (75)$$

where $\mathbf{Q}_{ij}$ are the 3×3 submatrices of $\mathbf{Q}$. The matrix $\mathbf{Q}$ is defined by Eq. (74) in terms of the known eigenvectors in the two media, so this allows us to solve for all the r/t coefficients. Computing $\mathbf{Q}$ seems to involve inverting a 6×6 matrix $\mathbf{W}_1$, but fortunately this can be avoided.

We note that $\mathbf{I}_2\mathbf{A}$ is symmetric and, taking the transpose of Eq. (71) times $\mathbf{I}_2$ [Eq. (38)], we can reduce it to

$$(\mathbf{W}^T\mathbf{I}_2)\mathbf{A} = \mathbf{p}_3(\mathbf{W}^T\mathbf{I}_2)$$

Postmultiplying this by $\mathbf{W}$, premultiplying Eq. (71) by $\mathbf{W}^T\mathbf{I}_2$, and subtracting, we find that

$$\mathbf{W}^T\mathbf{I}_2\mathbf{W} = \mathbf{K} \quad (76)$$

say, must be diagonal. The eigenvector columns of $\mathbf{W}$ are

$$\mathbf{w} = w_E \begin{pmatrix} \hat{\mathbf{g}}_E \\ -p_k c_{3k} \hat{\mathbf{g}}_E \end{pmatrix} \quad (77)$$

where w_E is an arbitrary normalization. From Eq. (76), we find that the diagonal elements of $\mathbf{K}$ are

$$K_E = -(2\rho U_3 w^2)_E \quad (78)$$

where Eq. (19) defines U_3 . Thus the required inverse matrix in Eq. (74) can be computed simply as

$$\mathbf{W}^{-1} = \mathbf{K}^{-1}\mathbf{W}^T\mathbf{I}_2 \quad (79)$$

If $w_E = 1/\sqrt{\pm 2\rho U_3}$, with the positive sign for $E=1$ to 3, and the negative sign for $E=4$ to 6, then $\mathbf{K} = \mathbf{K}^{-1} = \mathbf{I}_3$. In general,

especially for evanescent waves, it is simpler to take $w_E = 1$, when $\mathbf{K}$ is defined by Eq. (78). It is important to remember that the normalization w_E (77) effects the numerical value of the r/t coefficient. An incident plane wave of unit amplitude $\hat{\mathbf{g}}_j$ converts as

$$\hat{\mathbf{g}}_j \rightarrow \frac{w_\ell}{w_j} \mathcal{T}_{\ell j} \hat{\mathbf{g}}_{kl} \quad (80)$$

where $\ell = l + 3(k-1)$, and $\{j, k, l\}$ is the coefficient triplet defined in Section 2.5.

Finally we need to prove the reciprocity of the r/t coefficients $\mathcal{T}$ [Eq. (75)] (Chapman, 1994). In the reciprocal rays, the slownesses in the plane of the interface are reversed and the matrix $\mathbf{A}$ becomes

$$\mathbf{A}' = \mathbf{A}(-p_\nu) \quad (81)$$

The eigensolution becomes

$$\mathbf{A}'\mathbf{W}' = -\mathbf{W}'\mathbf{p}_3 \quad (82)$$

where the change of sign occurs as the slowness surface has point symmetry. The revised eigenvectors, $\mathbf{W}'$, are related by

$$\mathbf{W}' = -\mathbf{I}_3\mathbf{W} \quad (83)$$

i.e., the traction components change sign. Importantly, the propagation directions of the columns of $\mathbf{W}'$ are reversed, so Eq. (72) becomes

$$\mathbf{W}'_1 \begin{pmatrix} \mathbf{I} & \mathbf{0} \\ \mathcal{T}'_{11} & \mathcal{T}'_{12} \end{pmatrix} = \mathbf{W}'_2 \begin{pmatrix} \mathcal{T}'_{21} & \mathcal{T}'_{22} \\ \mathbf{0} & \mathbf{I} \end{pmatrix} \quad (84)$$

Taking the transpose of Eq. (84) and multiplying by $\mathbf{I}_1$ times (72) we obtain

$$\begin{aligned} \begin{pmatrix} \mathbf{I} & \mathcal{T}'_{11}^T \\ \mathbf{0} & \mathcal{T}'_{12}^T \end{pmatrix} \mathbf{W}'_1{}^T \mathbf{I}_1 \mathbf{W}_1 \begin{pmatrix} \mathcal{T}_{11} & \mathcal{T}_{12} \\ \mathbf{I} & \mathbf{0} \end{pmatrix} \\ = \begin{pmatrix} \mathcal{T}_{21}^T & \mathbf{0} \\ \mathcal{T}_{22}^T & \mathbf{I} \end{pmatrix} \mathbf{W}'_2{}^T \mathbf{I}_1 \mathbf{W}_2 \begin{pmatrix} \mathbf{0} & \mathbf{I} \\ \mathcal{T}_{21} & \mathcal{T}_{22} \end{pmatrix} \end{aligned} \quad (85)$$

Using Eq. (83), it is straightforward to simplify this as

$$\begin{aligned} \mathbf{W}'^T \mathbf{I}_1 \mathbf{W} &= -\mathbf{W}^T \mathbf{I}_3^T \mathbf{I}_1 \mathbf{W} = \mathbf{W}^T \mathbf{I}_2 \mathbf{W} = \mathbf{K} \\ &= \begin{pmatrix} \mathbf{K}_+ & \mathbf{0} \\ \mathbf{0} & \mathbf{K}_- \end{pmatrix} \end{aligned} \quad (86)$$

where we have expanded the matrix (76) into diagonal 3×3 submatrices for the positive and negative traveling waves. Then expanding Eq. (85), it is seen to be equivalent to

$$\mathcal{T}' = \begin{pmatrix} \mathbf{K}_{1-}^{-1} & \mathbf{0} \\ \mathbf{0} & -\mathbf{K}_{2+}^{-1} \end{pmatrix} \mathcal{T}^T \begin{pmatrix} -\mathbf{K}_{1+} & \mathbf{0} \\ \mathbf{0} & \mathbf{K}_{2-} \end{pmatrix} \quad (87)$$

which is the reciprocity result for the r/t coefficients. If the eigenvectors are normalized so that $\mathbf{K} = \mathbf{I}_3$, then this simplifies to $\mathcal{T}' = \mathcal{T}^T$.

2.9 The Ray Green Function

In practice, we do not need to solve for the complete dynamic propagator [Eq. (42)]. For a point source, all we need is solutions with initial conditions

$$\mathbf{y}(T_0) = \begin{pmatrix} 0 \\ \partial \mathbf{p}_0 / \partial q_\nu \end{pmatrix} \quad (88)$$

i.e., perturbations of the direction of the initial slowness $\mathbf{p}_0$. The ray parameters, q_ν , parametrize the source slowness surface, e.g., the polar angles. The solutions obtained directly are then

$$\frac{\partial \mathbf{x}}{\partial q_\nu} = \mathbf{P}_{xp} \frac{\partial \mathbf{p}_0}{\partial q_\nu} \quad (89)$$

Alternatively, we can use a basis vector in the wavefront, when the dynamic equations (37) can be rewritten as a 4×4 system, but numerically it is probably just as simple to use cartesian coordinates and find two or four solutions of the 6×6 system of Eq. (37). This equation can also be reduced to a nonlinear equation for J , but again it is probably easier to work with system (37), which is relatively simple algebraically and computationally. Furthermore, quantities other than J alone are needed for Maslov asymptotic ray theory.

Near a point source, the approximate solution of Eq. (37) gives $\mathbf{P}_{xp} \simeq \mathbf{R}_0(T - T_0)$. Using this in Eqs. (89) and (31), Kendall *et al.* (1992) have shown, by comparison with the exact solution for a point force $\mathbf{f}_0$ in homogeneous media (Buchwald, 1959; Lighthill, 1960; Duff, 1960; Burridge, 1967), that Eq. (35) becomes

$$V_E^{(0)} = \frac{1}{4\pi} \left(\left| \frac{\partial \mathbf{p}_0}{\partial q_1} \times \frac{\partial \mathbf{p}_0}{\partial q_2} \right| / \rho_0 \rho u U_0 J \right)^{1/2} \hat{\mathbf{g}}_0^T \mathbf{f}_0 \quad (90)$$

Numerically, this is all that is needed as Eq. (89) gives the factor uJ [Eq. (31)]. Although sufficient for the numerical solution, theoretically it is useful to analyze the system further to eliminate the arbitrary parametrization q_ν , and prove reciprocity. At the receiver, Kendall *et al.* (1992) have shown that with Eq. (89), the required expression Eq. (31) can be written

$$uJ = \mathbf{U} \cdot \left(\frac{\partial \mathbf{x}}{\partial q_1} \times \frac{\partial \mathbf{x}}{\partial q_2} \right) = \frac{1}{U_0} \left| \frac{\partial \mathbf{p}_0}{\partial q_1} \times \frac{\partial \mathbf{p}_0}{\partial q_2} \right| \mathcal{R} \quad (91)$$

where

$$\mathcal{R}(\mathbf{x}, \mathbf{x}_0) = \mathbf{U}_0^T \text{adj}(\mathbf{P}_{xp}) \mathbf{U} = |\mathbf{P}_{xp}| \mathbf{U}_0^T \mathbf{P}_{xp}^{-1} \mathbf{U} \quad (92)$$

Combining these results (90) and (91), and introducing the product of appropriate r/t coefficients for the ray history, the

amplitude coefficient for the dyadic Green function is

$$\underline{\mathbf{V}}^{(0)} = \frac{e^{-i(\pi/2)\text{sgn}(\omega)\sigma(\mathbf{x}, \mathcal{L}_n)} (\prod \mathcal{T}_{\ell j}) \hat{\mathbf{g}} \hat{\mathbf{g}}_0^T}{4\pi(\rho(\mathbf{x})\rho(\mathbf{x}_0)|\mathcal{R}|)^{1/2}} \quad (93)$$

(we use an underline to indicate a Green function, which for the velocity field for a point force can be treated as a 3×3 matrix). The KMAH index, $\sigma(\mathbf{x}, \mathcal{L}_n)$, is introduced as J in Eq. (90) and $\mathcal{R}$ in Eq. (91) may be negative. Symbolically we have written the product of r/t coefficients as simply $\prod \mathcal{T}_{\ell j}$ where $\mathcal{T}_{\ell j}$ is an element of the matrix $\mathcal{T}$ with the normalization $w_E = 1/\sqrt{\pm 2\rho U_3}$ —the values of ℓ and j [as defined in Eqn. (80), etc.] and the elastic parameters used for the $\mathcal{T}_{\ell j}$ depend on the ray history and the ray path $\mathcal{L}_n$.

It is interesting to verify the behavior of the Green function (93) just before and just after an interface. The relevant factors in Eq. (93) convert as

$$\frac{\hat{\mathbf{g}}_j}{(\rho_j|\mathcal{R}_j|)^{1/2}} \rightarrow \mathcal{T}_{\ell j} \frac{\hat{\mathbf{g}}_{kl}}{(\rho_k|\mathcal{R}_{kl}|)^{1/2}} \quad (94)$$

where $\{j, k, l\}$ is the coefficient triplet. Using Eqs. (56) and (91), it is straightforward to see that this is exactly equivalent to Eq. (80).

The dynamic ray equations, e.g., Eq. (32), break down at caustics where $J=0$. Only by using a more complete wave theory or an extension of ray theory, e.g., Maslov asymptotic ray theory (Section 4.1), can we determine how the ray solutions connect through the caustic. In fact Eq. (90) remains valid provided the correct root is taken for $J^{-1/2}$ and this is introduced by the KMAH index. The KMAH index counts the caustics along the ray (incrementing by 1 at each first-order zero—line caustic—of $\mathbf{P}_{xp}$, and by 2 at a second-order zero—point caustic). In anisotropic media, it may also decrease depending on the properties of the matrix $\mathbf{R}$ in the dynamic system (37) (Lewis, 1965; Garmany, 1988; Klimesš, 1997; Bakker, 1998). Although the KMAH index counts zeros of the spreading matrix $\mathbf{P}_{xp}$, i.e., changes in sign of eigenvalues, result (43) is not sufficient to establish reciprocity of the KMAH index as the signature of the matrix only counts zeros in modulo arithmetic (although, as only $\exp(-i\pi\sigma/2)$ is needed, it is sufficient for reciprocity of the Green function). Nevertheless, we can easily argue that the KMAH index is reciprocal. Consider a short ray with no caustics, e.g., with the receiver near the source so we can approximate by straight rays. The KMAH index is obviously reciprocal (normally zero). If we gradually move the receiver away from the source along the ray path $\mathcal{L}_n$, result (43) guarantees that the KMAH index for the ray and its reciprocal will increment at the same time (note that this is not a trivial argument as the caustic will always occur at the receiver point, different for the ray and its reciprocal). Thus although Eq. (43) only guarantees that the KMAH indices are equal in modulo arithmetic, growing the

ray and its reciprocal from nothing proves that the KMAH index is exactly reciprocal.

Substituting Eq. (93) in Eq. (4), we obtain the time-domain, zeroth-order ray theory Green function,

$$\underline{\mathbf{v}}(t, \mathbf{x}; \mathbf{x}_0) \simeq \frac{1}{4\pi} \text{Re} \left[\Delta(t - T(\mathbf{x}, \mathcal{L}_n)) e^{-i(\pi/2)\sigma(\mathbf{x}, \mathcal{L}_n)} \times \left(\prod \mathcal{T}_{\ell_j} \right) (\rho(\mathbf{x})\rho(\mathbf{x}_0)|\mathcal{R}|)^{-1/2} \hat{\mathbf{g}} \hat{\mathbf{g}}_0^T \right] \quad (95)$$

where $\Delta(t) = \delta(t) - i/\pi t$ is the analytic delta function. In a homogeneous, isotropic medium this reduces to the standard result (Aki and Richards, 1980, Ch. 4)

$$\underline{\mathbf{v}}(t, \mathbf{x}; \mathbf{x}_0) = \frac{\delta(t - T) \hat{\mathbf{g}} \hat{\mathbf{g}}_0^T}{4\pi\rho U^2 R} \quad (96)$$

where $R = |\mathbf{x} - \mathbf{x}_0|$ and $T = R/U$.

The reciprocity of Eq. (95) is established as $T(\mathbf{x}, \mathcal{L}_n)$ is obviously reciprocal, the KMAH index is reciprocal from the argument above, the r/t coefficients are reciprocal from Eq. (87), and $\mathcal{R}$ is reciprocal from Eq. (43). Thus,

$$\underline{\mathbf{v}}(t, \mathbf{x}_0; \mathbf{x}) = \underline{\mathbf{v}}^T(t, \mathbf{x}; \mathbf{x}_0) \quad (97)$$

In using Eq. (95), it is important that a consistent rule is used to define the sign of the polarization $\hat{\mathbf{g}}$ such that $\hat{\mathbf{g}} \rightarrow \hat{\mathbf{g}}_0$ as $\mathbf{x} \rightarrow \mathbf{x}_0$ —the sign is ambiguous in the eigenvector equation (15) or Hamiltonian (16). Thus, typically we choose $\hat{\mathbf{g}} \simeq u\mathbf{p}$ for the qP ray, but this means that in the reciprocal ray (97), both polarizations change sign.

3. Specializations to Simpler Earth Models

3.1 Isotropic Ray Theory

We now specialize the general, anisotropic results to those for an isotropic model. Although it simplifies the kinematic ray equations, the shear waves are now degenerate.

In an isotropic medium, the elastic tensor is given by

$$c_{ijkl} = \lambda \delta_{ij} \delta_{kl} + \mu (\delta_{ik} \delta_{jl} + \delta_{il} \delta_{jk}) \quad (98)$$

where λ and μ are the Lamé parameters. The matrices $\mathbf{c}_{jk}$ reduce to

$$\mathbf{c}_{11} = \begin{pmatrix} \lambda + 2\mu & 0 & 0 \\ 0 & \mu & 0 \\ 0 & 0 & \mu \end{pmatrix}, \quad \mathbf{c}_{23} = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & \lambda \\ 0 & \mu & 0 \end{pmatrix}, \quad \text{etc.} \quad (99)$$

3.1.1 The Isotropic Eikonal

As the medium is isotropic, we can choose any propagation direction to determine the Hamiltonian. Let us choose

$$\mathbf{p} = (0 \quad 0 \quad p)^T \quad (100)$$

Then

$$p_j p_k \mathbf{c}_{jk} = p^2 \mathbf{c}_{33} = \begin{pmatrix} \mu p^2 & 0 & 0 \\ 0 & \mu p^2 & 0 \\ 0 & 0 & (\lambda + 2\mu) p^2 \end{pmatrix} \quad (101)$$

Thus the Hamiltonians are

$$H_1 = H_2 = \frac{1}{2}(\beta^2 p_i p_i - 1), \quad H_3 = \frac{1}{2}(\alpha^2 p_i p_i - 1) \quad (102)$$

where the P and S wave velocities are

$$\alpha = \sqrt{\frac{\lambda + 2\mu}{\rho}} \quad \text{and} \quad \beta = \sqrt{\frac{\mu}{\rho}} \quad (103)$$

(for definiteness, we always choose $I = 3$ as the P wave).

Using the isotropic Hamiltonian (102), the kinematic ray equations (19) and (20) simplify to

$$\frac{d\mathbf{x}}{dT} = U^2 \mathbf{p} \quad (104)$$

$$\frac{d\mathbf{p}}{dT} = -\frac{\nabla U}{U} \quad (105)$$

The P wave solution requires $u = U = \alpha$ and $\hat{\mathbf{g}}_3 = \alpha \mathbf{p}$, i.e., the wave is longitudinal. The S wave solution requires $u = U = \beta$ and the polarizations are perpendicular to the ray direction, i.e., $\hat{\mathbf{g}}_\nu \cdot \mathbf{p} = 0$ and the wave is transverse. However, the eigenequation (15) is degenerate and does not determine the S polarization uniquely. To find the shear wave polarizations in isotropic media, we must consider the equation (9) with $m = 1$.

For future use, let us give some useful relationships involving the polarization vectors and elastic matrices:

$$p_j \mathbf{c}_{jk} \hat{\mathbf{g}}_3 = (\lambda + \mu) p_k \hat{\mathbf{g}}_3 + \frac{\mu}{\alpha} \hat{\mathbf{e}}_k \quad (106)$$

$$p_j \mathbf{c}_{kj} \hat{\mathbf{g}}_3 = 2\mu p_k \hat{\mathbf{g}}_3 + \frac{\lambda}{\alpha} \hat{\mathbf{e}}_k \quad (107)$$

$$p_j \mathbf{c}_{jk} \hat{\mathbf{g}}_\nu = \mu p_k \hat{\mathbf{g}}_\nu + \lambda (\hat{\mathbf{g}}_\nu \cdot \hat{\mathbf{e}}_k) \mathbf{p} \quad (108)$$

$$p_j \mathbf{c}_{kj} \hat{\mathbf{g}}_\nu = \mu p_k \hat{\mathbf{g}}_\nu + \mu (\hat{\mathbf{g}}_\nu \cdot \hat{\mathbf{e}}_k) \mathbf{p} \quad (109)$$

where $\hat{\mathbf{e}}_k$ are the unit cartesian coordinate vectors. These results can easily be derived using Eq. (99).

3.1.2 The Isotropic Transport Equation and Shear Ray Polarization

In the equation (9) with $m = 1$, we expand $\mathbf{V}^{(1)}$ according to Eq. (23). For a shear ray, the equation reduces to

$$\bar{\mathbf{M}}(\mathbf{V}^{(0)}, \mathbf{T}_j^{(0)}) = \rho \left(\frac{\beta^2}{\alpha^2} - 1 \right) V_3^{(1)} \hat{\mathbf{g}}_3 \quad (110)$$

Premultiplying by $\hat{\mathbf{g}}_\nu^T$, and considering one shear wave, $\mathbf{V}^{(0)} = V_1^{(0)} \hat{\mathbf{g}}_1$, say, without loss in generality we obtain

$$\hat{\mathbf{g}}_\nu^T \mathbf{M}(V_1^{(0)} \hat{\mathbf{g}}_1) = 0 \quad (111)$$

Using Eqs. (108) and (109) in (111) and expanding, we obtain

$$\delta_{1\nu} (2\mu \mathbf{p} \cdot \nabla V_1^{(0)} + V_1^{(0)} \mathbf{p} \cdot \nabla \mu + \mu V_1^{(0)} \nabla \cdot \mathbf{p}) + 2\rho V_1^{(0)} \hat{\mathbf{g}}_\nu^T \frac{d\hat{\mathbf{g}}_1}{dT} = 0 \quad (112)$$

where we have used the orthonormality of the eigenvectors, and $\beta^2 \mathbf{p} \cdot \nabla = d/dT$ to simplify the final term.

When $\nu = 1$, this gives

$$\begin{aligned} 2\mu \mathbf{p} \cdot \nabla V_1^{(0)} + V_1^{(0)} \mathbf{p} \cdot \nabla \mu + \mu V_1^{(0)} \nabla \cdot \mathbf{p} \\ = \frac{1}{V_1^{(0)}} \nabla \cdot (\rho \beta^2 V_1^{(0)2} \mathbf{p}) = 0 \end{aligned} \quad (113)$$

which is the isotropic transport equation equivalent to Eq. (29) with $\mathbf{U} = \beta^2 \mathbf{p}$ and $\xi^{(0)} = 0$.

When $\nu = 2$, Eq. (112) is simply

$$2\rho V_1^{(0)} \hat{\mathbf{g}}_2^T \frac{d\hat{\mathbf{g}}_1}{dT} = 0 \quad (114)$$

For $\hat{\mathbf{g}}_1$ and $\hat{\mathbf{g}}_2$ to be the polarizations of the independent shear waves, they must satisfy this differential equation (114). Thus the change in $\hat{\mathbf{g}}_1$, which is necessarily orthogonal to itself (as the vector is normalized), is also orthogonal to $\hat{\mathbf{g}}_2$. It can only be in the $\hat{\mathbf{g}}_3$ direction, i.e.,

$$\frac{d\hat{\mathbf{g}}_\nu}{dT} = a \hat{\mathbf{g}}_3 \quad (115)$$

(generalized for both $\nu = 1$ and 2). Thus the shear polarization only changes in the ray direction and does not twist about it. It remains to find a in Eq. (115), which is determined from the geometrical condition that $\hat{\mathbf{g}}_\nu$ remain transverse:

$$a = \beta \mathbf{p}^T \frac{d\hat{\mathbf{g}}_\nu}{dT} = -\beta \hat{\mathbf{g}}_\nu^T \frac{d\mathbf{p}}{dT} = \hat{\mathbf{g}}_\nu^T \nabla \beta \quad (116)$$

using Eq. (105). Thus,

$$\frac{d\hat{\mathbf{g}}_\nu}{dT} = (\hat{\mathbf{g}}_\nu^T \nabla \beta) \hat{\mathbf{g}}_3 \quad (117)$$

In the literature this result has been proved indirectly using the equations for the normal and binormal of the ray path,

and relating the shear polarization to the torsion of the ray (Popov and Pšenčík, 1978; Červený and Hron, 1980; Červený, 1985). The above direct proof is due to Pšenčík (personal communication, 1998) and avoids ever having to discuss these other matters.

Having achieved the decoupling of the shear wave amplitude coefficients by using the shear wave polarization vectors as the basis, the analysis for higher-order terms in anisotropic media remains valid for isotropic media (Červený and Hron, 1980): for the P ray, we have two additional terms and one principal component; for S rays, we have one additional term, and two principal components, both determined using Eq. (34).

In isotropic media, the first-order additional terms [Eq. (25) with $m = 1$] can be written in relatively simple forms (Eisner and Pšenčík, 1996). For P we obtain

$$\begin{aligned} V_\nu^{(1)} &= \frac{\alpha^2 \hat{\mathbf{g}}_\nu^T}{\rho(\beta^2 - \alpha^2)} \mathbf{M}(V_3^{(0)} \hat{\mathbf{g}}_3) \\ &= -\hat{\mathbf{g}}_\nu^T \left(\alpha \frac{\partial V_3^{(0)}}{\partial g_\nu} + \frac{V_3^{(0)}}{\alpha^2 - \beta^2} \left[(\alpha^2 - \beta^2) \nabla \alpha - 4\alpha\beta \nabla \beta \right. \right. \\ &\quad \left. \left. + \alpha(\alpha^2 - 2\beta^2) \nabla(\ln \rho) \right] \right) \end{aligned} \quad (118)$$

(g_ν is a coordinate in the direction $\hat{\mathbf{g}}_\nu$). Similarly for S waves, the additional term is

$$\begin{aligned} V_\nu^{(1)} &= \frac{\beta^2 \hat{\mathbf{g}}_\nu^T}{\rho(\alpha^2 - \beta^2)} \mathbf{M}(V_\nu^{(0)} \hat{\mathbf{g}}_\nu) \\ &= \hat{\mathbf{g}}_\nu^T \left(\beta \frac{\partial V_\nu^{(0)}}{\partial g_\nu} + \frac{V_\nu^{(0)}}{\alpha^2 - \beta^2} \left[(\alpha^2 + 3\beta^2) \nabla \beta + \beta^3 \nabla(\ln \rho) \right] \right) \end{aligned} \quad (119)$$

Apart from using Eqs. (106) to (109), (117), the orthonormality of the polarization vectors, and kinematic ray results, it is useful to note

$$\frac{d\hat{\mathbf{g}}_3}{dT} = -(\hat{\mathbf{g}}_\nu \cdot \nabla U) \hat{\mathbf{g}}_\nu \quad (120)$$

$$\nabla \cdot \hat{\mathbf{g}}_\nu = \frac{1}{U} (\hat{\mathbf{g}}_\nu \cdot \nabla U) \quad (121)$$

3.2 1D and 2D Media

Naturally the ray equations simplify if the heterogeneity in the model is restricted to one or two dimensions. The appropriate ray equation, Eq. (20) or Eq. (105), immediately reduces to the conservation of the corresponding slowness component:

$$p_\nu = \text{constant} \quad (122)$$

Although there is some simplification of the other equations in 2D, only in 1D media are these really significant, circumventing the solution of ordinary differential equations. Thus if the

medium depends only on x_3 , then Eq. (19) is

$$\frac{dx_i}{dT} = U_i(p_1, p_2, x_3) \quad (123)$$

as p_3 can be found from the constraint (18). Then for $\nu = 1$ or 2 we have

$$x_\nu(p_1, p_2, x_3) = \int \frac{U_\nu}{U_3} dx_3 \quad (124)$$

$$T(p_1, p_2, x_3) = \int \frac{1}{U_3} dx_3 \quad (125)$$

where the depth integral is over all segments of the ray arranged so that dx_3/U_3 is positive (in anisotropic media it is possible for U_ν to be negative—Shearer and Chapman, 1988).

In isotropic media, we have axial symmetry and, without loss in generality, we can take $p_2 = x_2 = 0$. Then Eqs. (124) and (125) reduce to the simple *ray integrals*,

$$x_1(p_1, 0, x_3) = \int \frac{p_1}{p_3} dx_3 = \int \tan i(x_3) dx_3 \quad (126)$$

$$T(p_1, 0, x_3) = \int \frac{1}{U^2 p_3} dx_3 = \int \frac{\sec i(x_3)}{U(x_3)} dx_3 \quad (127)$$

used in layered media. The slowness vector is

$$\mathbf{p} = \frac{1}{U(x_3)} \begin{pmatrix} \sin i(x_3) \\ 0 \\ \cos i(x_3) \end{pmatrix} \quad (128)$$

where p_1 is conserved and $i(x_3)$ is the angle the ray makes with the vertical. Using $q_1 = p_1$ and $q_2 = \phi$ (the azimuth), it is straightforward to reduce the amplitude coefficient (90) to

$$V_E^{(0)} = \frac{1}{4\pi} \left(\rho_0 \rho U_0 U \cos i_0 \cos i \frac{x_1}{p_1} \left| \frac{dx_1}{dp_1} \right| \right)^{-1/2} \hat{\mathbf{g}}_0^T \mathbf{f}_0 \quad (129)$$

where dx_1/dp_1 can be obtained from Eq. (126) [but care must be taken differentiating (126) if the lower limit is a turning point where $p_3 = 0$, i.e., when $p_1 U(x_3) = 1$ and $i(x_3) = \pi/2$]. This expression (129) remains valid at $x_1 = 0$ using l'Hopital's rule to replace $x_1/p_1 \rightarrow dx_1/dp_1$. It is interesting to note that on a symmetry plane in a 2D model, i.e., 2.5D wave propagation, the expression (129) is still valid provided the factor x_1/p_1 is replaced by $dx_2/dp_2 = \int U^2 dT$ (Brokešova, 1992—the kinematic and dynamic differential equations need only be solved in 2D), which is identical in 1D.

The equivalent results in a spherically symmetric Earth can be obtained by the conformal, Earth flattening transformation $x_1 = r_0 \theta$, $r/r_0 = \exp(x_3/r_0)$, and $U(r) = rU(z)/r_0$ (r_0 is a reference radius). The conserved “horizontal” slowness is

$$p_\theta = \frac{r \sin i(r)}{r_0 U(r)} \quad (130)$$

corresponding to the angular slowness, and the angular range and travel time are

$$\theta(p_\theta, r) = \int \tan i(r) \frac{dr}{r} \quad (131)$$

$$T(p_\theta, r) = \int \frac{\sec i(r)}{U(r)} dr \quad (132)$$

These correspond to the ray integrals of Bullen (1963, §7.2.2) where $r_0 p_\theta$ is Bullen's ray parameter.

4. Generalizations to Ray Singularities

Although ray theory has wide application, there are many circumstances in which it breaks down. Nevertheless, ray theory extensions can often be used to fill these gaps with minimal extra computation or expense. In this section we briefly discuss three generalizations of ray theory: Maslov asymptotic ray theory, which remains valid at caustics, i.e., when $\mathcal{R} = 0$ in Eq. (93); Kirchhoff surface integral method, which models reflections from rough surfaces, i.e., $(\prod \mathcal{T}_{\ell_j})/|\mathcal{R}|^{-1/2}$ varies rapidly in $\mathbf{V}^{(0)}$ [Eq. (93)]; and quasi-isotropic ray theory, which remains valid when the velocities of the $q\mathcal{S}$ rays are similar, i.e., $H_N \rightarrow 0$ in Eq. (25). Necessarily, the discussion is brief and further details can be found in the specialist publications. Another useful generalization, the Born scattering volume integral method and its generalizations, is not included but is a natural extension of the Kirchhoff method from surface to volume integrals (Chapman and Coates, 1994; de Hoop and Bleistein, 1997; Ursin and Tygel, 1997; Spencer *et al.*, 1997).

4.1 Maslov Asymptotic Ray Theory

As already noted, the ray theory Green function (95) breaks down at caustics where $\mathcal{R} = 0$ and rays are focused to a point or line. Maslov asymptotic ray theory avoids this problem by generalizing the ansatz of ray theory with an integration over neighboring rays, by analogy with transform methods. In this section, we follow the development in Chapman and Keers (2002) and write the ansatz for Maslov asymptotic ray theory as

$$\mathbf{v}(\omega, \mathbf{x}; \mathbf{x}_0) \simeq |\omega| f(\omega) \sum_n \iint \tilde{\mathbf{V}}^{(0)}(\mathbf{q}, \mathcal{L}_n) \mathbf{e}^{i\omega\theta(\mathbf{q}, \mathcal{L}_n)} d\mathbf{q} \quad (133)$$

where $\mathbf{q} = (q_1, q_2)^T$ is a ray parameter vector. Note that the summation is now only over ray types not rays, i.e., as defined by the sequence of ray segments and r/t coefficients. If multipathing of rays of the same type exists, i.e., at different take-off angles, then it is contained within the integral. For brevity, in what follows we drop the ray type summation. The factor $|\omega|$ is introduced as with hindsight it makes $\tilde{\mathbf{V}}^{(0)}$ independent of

frequency (we assume frequency is real and the modulus is required so $\underline{v}(t, \mathbf{x}; \mathbf{x}_0)$ is real).

The Maslov integral is normally written as an integral over (components of) slowness at the receiver. However, difficulties arise later as multiple rays may exist with the same slowness. It is simpler to start with an integral that is single valued, i.e., there is one-to-one mapping between $\mathbf{q}$ and the rays. Locally, the integrands will only differ by a Jacobian, but using $\mathbf{q}$ we avoid later complications. The integral (133) is only an ansatz, so our choice of variable is not critical.

How do we define $\tilde{\mathbf{V}}^{(0)}$ and θ in Eq. (133)? There are many choices (see Kendall and Thomson, 1993, etc.). All that is certainly required is that for high enough frequency, Eq. (133) agrees (asymptotically) with ray theory [Eq. (3)], when the latter is valid. And for high enough frequency, ray theory is valid almost everywhere as it only breaks down on caustic surfaces and points. So first we choose $\tilde{\mathbf{V}}^{(0)}$ and θ so that asymptotically Eq. (133) agrees with ray theory almost everywhere as $\omega \rightarrow \infty$. Then we argue that because with this choice of $\tilde{\mathbf{V}}^{(0)}$ and θ , the integral is valid everywhere and behaves smoothly at finite frequencies, as must the exact solution, so Eq. (133) will be a useful solution at caustics and at finite frequencies.

A more sophisticated argument using pseudo-differential and Fourier integral operators can be developed by substituting Eq. (133) in the wave equations and finding the asymptotic behaviour for $\tilde{\mathbf{V}}$ (see Kendall and Thomson, 1993, and references therein). The result for the leading term, $\tilde{\mathbf{V}}^{(0)}$, must be the same using either argument. Higher-order terms are rarely useful or even evaluated. Therefore we follow the simpler approach.

Shooting a ray with parameters $\mathbf{q}$ to a target surface we obtain a traveltime, $\tilde{T}(\mathbf{q}, \mathcal{L}_n)$ and an end-point, $\tilde{\mathbf{X}}(\mathbf{q}, \mathcal{L}_n)$. Normally the target surface is a plane through the receiver(s), but some other end-condition is possible. Note that $\tilde{T}$ and $\tilde{\mathbf{X}}$ are functions of the source and ray parameters, as in ray shooting. In general we use a tilde to indicate variables on the target surface, e.g., $\tilde{\mathbf{p}}(\mathbf{q}, \mathcal{L}_n)$, the ray slowness on the target surface.

One choice for θ (by analogy with transform methods) is

$$\theta(\mathbf{q}, \mathcal{L}_n) = \tilde{T}(\mathbf{q}, \mathcal{L}_n) + \tilde{\mathbf{p}}^T(\mathbf{q}, \mathcal{L}_n) (\mathbf{x} - \tilde{\mathbf{X}}(\mathbf{q}, \mathcal{L}_n)) \quad (134)$$

The integral (133) has a stationary-phase point when $\mathbf{x} = \tilde{\mathbf{X}}(\mathbf{q}, \mathcal{L}_n)$, at which θ is the travel time, i.e., $T(\tilde{\mathbf{X}}, \mathcal{L}_n) = \theta(\mathbf{q}, \mathcal{L}_n) = \tilde{T}(\mathbf{q}, \mathcal{L}_n)$, i.e., $\mathbf{q}$ are the ray parameters that solve the two-point ray problem. Evaluating (133) by the second-order, stationary-phase method, and comparing with the ray result (3), we find

$$\begin{aligned} \tilde{\mathbf{V}}^{(0)}(\mathbf{q}, \mathcal{L}_n) &= 2\pi \underline{\mathbf{V}}^{(0)}(\tilde{\mathbf{X}}, \mathcal{L}_n) \|\nabla_{\mathbf{q}}(\nabla_{\mathbf{q}}\theta)^T\|^{1/2} \\ &\times e^{-i(\pi/4)\text{sgn}(\omega \nabla_{\mathbf{q}}(\nabla_{\mathbf{q}}\theta)^T)} \end{aligned} \quad (135)$$

where the signature (sgn) of the matrix is the number of positive eigenvalues minus the number of negative eigenvalues

(2, 0, or -2 as the matrix is 2×2 —we treat $\nabla_{\mathbf{q}}$ as 2×1). Thus with Eqs. (134) and (135) we have defined the integrand of (133) in such a way that it reduces, asymptotically, to ray theory [Eq. (3)] when the latter is valid. We now discuss some of the practical aspects of computing these terms.

Using the results in Section 2, it is straightforward to compute θ and $\underline{\mathbf{V}}^{(0)}$ for any $\mathbf{q}$. The more complicated term is the 2×2 matrix

$$\nabla_{\mathbf{q}}(\nabla_{\mathbf{q}}\theta)^T = -(\nabla_{\mathbf{q}}\tilde{\mathbf{p}}^T)(\nabla_{\mathbf{q}}\tilde{\mathbf{X}}^T)^T \quad (136)$$

as $\tilde{\mathbf{p}}$ and $\tilde{\mathbf{X}}$ are on the target surface not the wavefront. Using the results of dynamic raytracing, we can compute the wavefront differentials

$$\begin{pmatrix} \mathbf{J}_{xp} \\ \mathbf{J}_{pp} \end{pmatrix} = \begin{pmatrix} \mathbf{P}_{xp} \\ \mathbf{P}_{pp} \end{pmatrix} \begin{pmatrix} \partial \mathbf{p}_0 / \partial q_1 & \partial \mathbf{p}_0 / \partial q_2 \end{pmatrix} \quad (137)$$

[cf. Eq. (89)—remember we normally compute the LHS directly from the paraxial ray equations (37) with appropriate initial conditions (88), rather than with the propagator]. The matrices $\mathbf{J}_{xp}$ and $\mathbf{J}_{pp}$ are 3×2 . In order to compute the target differentials in Eq. (136), the wavefront differentials must be modified for the extra ray path. If $\hat{\mathbf{n}}$ is the normal to the target surface, then [cf. matrix $\mathbf{F}_1$ (54)]

$$(\nabla_{\mathbf{q}}\tilde{\mathbf{X}}^T)^T = \left(\mathbf{I} - \frac{\dot{\mathbf{x}}\hat{\mathbf{n}}^T}{\dot{\mathbf{x}}^T\hat{\mathbf{n}}} \right) \mathbf{J}_{xp} \quad (138)$$

where the second term is designed to be in the ray direction, $\mathbf{U}$, and to make the differential in the target surface, i.e., orthogonal to $\hat{\mathbf{n}}$. The slowness differential is modified by the extra ray path, and using Eq. (20) we obtain the 2×3 matrix [cf. matrix $\mathbf{F}_2$ (54) and (53)]

$$\nabla_{\mathbf{q}}\tilde{\mathbf{p}}^T = \left(\mathbf{J}_{pp} - \frac{\dot{\mathbf{p}}\hat{\mathbf{n}}^T}{\dot{\mathbf{x}}^T\hat{\mathbf{n}}} \mathbf{J}_{xp} \right)^T \quad (139)$$

Combining Eqs. (138) and (139) for (136), we can compute Eq. (135).

Having obtained θ and $\tilde{\mathbf{V}}^{(0)}$ using the results of normal ray shooting, they can be used to evaluate (133). Rather than evaluate the spectrum, it is easier to compute the time-domain response directly. Evaluating the inverse Fourier transform of Eq. (133), we can change the order of integration and reduce the triple integral without approximation, assuming θ is real. The result is

$$\underline{v}(t, \mathbf{x}; \mathbf{x}_0) = -\frac{d}{dt} \text{Im} \left[F(t) * \int_{t=\theta} \frac{\tilde{\mathbf{V}}^{(0)}}{|\nabla_{\mathbf{q}}\theta|} dq \right] \quad (140)$$

$$\simeq -\frac{1}{2\Delta t} \frac{d}{dt} \text{Im} \left[F(t) * \iint_{t=\theta \pm \Delta t} \tilde{\mathbf{V}}^{(0)} d\mathbf{q} \right] \quad (141)$$

FIGURE 5 The bandlimited Maslov integral. The amplitude, $\tilde{\mathbf{v}}^{(0)}$, is integrated over the strips defined by $t \pm \Delta t$ of the θ function. Within the triangular ray tube (the vertices of the triangles correspond to rays), the θ and $\tilde{\mathbf{v}}^{(0)}$ functions are linearly interpolated. The same diagram applies to the Kirchhoff integral, where the triangular elements form the interface.

where Eq. (140) is the impulse result and Eq. (141) is the bandlimited result. The integral in Eq. (140) is evaluated along the line in the $\mathbf{q}$ domain where $t = \theta$. The bandlimited result has been convolved with a boxcar $2\Delta t$ long. The integral in Eq. (141) is evaluated over the strip defined by $t = \theta \pm \Delta t$ in the $\mathbf{q}$ domain (Fig. 5). Because $\tilde{\mathbf{v}}^{(0)}$ normally varies smoothly, this area integral is easily evaluated. An efficient algorithm, described in Spencer *et al.* (1997), is to linearly interpolate within triangular ray tubes in the $\mathbf{q}$ domain (Fig. 5). Details of the algorithm are given in the Appendix.

4.2 Kirchhoff Surface Integral Method

The ray method describes the high-frequency behavior of reflections from interfaces. It takes into account the amplitude changes due to the r/t coefficients, and the spreading changes that may occur due to the change in ray type and the curvature of the interface. However, diffracted signals that occur due to roughness and discontinuities in the interface are not modeled. The Kirchhoff surface integral method is a useful generalization of ray theory that models, at least approximately, such signals by integrating over non-specular reflections on the interface. Rays are traced from the source (or by reciprocity, from the receiver to the interface) without satisfying Snell's law at the interface. The basic method has been described by Bleistein (1984, p. 282), and Frazer and Sen (1985) and references therein to earlier papers have described its application to seismology for acoustic or isotropic media. Recent papers, e.g., de Hoop and Bleistein (1997) and Ursin and Tygel (1997), have extended the method to anisotropic media.

The representation (Betti's) theorem gives the reflected signal in terms of a surface integral (Aki and Richards, 1980,

p. 28). Thus, following the standard method, we have for the scattered signal

$$\mathbf{v}(\omega, \mathbf{x}; \mathbf{x}_0) = -i\omega \int_S \left[\mathbf{t}_m^T(\omega, \boldsymbol{\zeta}; \mathbf{x}) \mathbf{v}(\omega, \boldsymbol{\zeta}; \mathbf{x}_0) - \mathbf{v}^T(\omega, \boldsymbol{\zeta}; \mathbf{x}) \mathbf{t}_m(\omega, \boldsymbol{\zeta}; \mathbf{x}_0) \right] \hat{n}_m d\mathbf{s} \quad (142)$$

where the point $\boldsymbol{\zeta}$ lies on the surface S of the integral and $d\mathbf{s}$ is the surface area element. The Green functions from the receiver—argument $(\omega, \boldsymbol{\zeta}; \mathbf{x})$ —are the free-space Green functions (Bleistein, 1984, p. 282), which we approximate by ray theory (Section 2.9),

$$\left(\frac{\mathbf{v}}{\mathbf{t}_m} \right) (\omega, \boldsymbol{\zeta}; \mathbf{x}) \simeq \frac{e^{i\omega T(\boldsymbol{\zeta}, \mathcal{L}_r) - i(\pi/2)\text{sgn}(\omega)\sigma(\boldsymbol{\zeta}, \mathcal{L}_r)}}{4\pi(\rho(\mathbf{x})\rho_r(\boldsymbol{\zeta})|\mathcal{R}(\boldsymbol{\zeta}, \mathcal{L}_r)|)^{1/2}} \left(\prod \mathcal{T}_{\ell_j}(\mathcal{L}_r) \right) \times \left(\begin{matrix} \hat{\mathbf{g}} \\ -\mathbf{Z}_m \hat{\mathbf{g}} \end{matrix} \right) (\boldsymbol{\zeta}, \mathcal{L}_r) \hat{\mathbf{g}}^T(\mathbf{x}, \mathcal{L}_r) \quad (143)$$

where

$$\mathbf{Z}_m(\boldsymbol{\zeta}, \mathcal{L}_r) = p_j(\boldsymbol{\zeta}, \mathcal{L}_r) \mathbf{c}_{mj}(\boldsymbol{\zeta}) \quad (144)$$

[from Eq. (6) with $m=0$] is a *matrix impedance* (Chapman and Coates, 1994). We use the shorthand $\mathcal{L}_r$ to indicate the ray path from $\mathbf{x}$ to $\boldsymbol{\zeta}$, subscript r to indicate the generated ray type, and for simplicity, omit a summation over multipathing and ray type. The product of coefficients is for interfaces between $\mathbf{x}$ and $\boldsymbol{\zeta}$ but not the interface at $\boldsymbol{\zeta}$.

We approximate $\mathbf{v}(\omega, \boldsymbol{\zeta}; \mathbf{x}_0)$ and $\mathbf{t}_m(\omega, \boldsymbol{\zeta}; \mathbf{x}_0)$ within the surface integral (142) by the ray theory values. Normally this is restricted to the reflected ray that matches the ray type to the receiver, but more generally we can include the incident wave and all three reflections (to model the complete, continuous displacement and traction on the interface). Thus using the free-space Green function from the source $\mathbf{x}_0$, we have

$$\left(\frac{\mathbf{v}}{\mathbf{t}_m} \right) (\omega, \boldsymbol{\zeta}; \mathbf{x}_0) \simeq \frac{e^{i\omega T(\boldsymbol{\zeta}, \mathcal{L}_s) - i(\pi/2)\text{sgn}(\omega)\sigma(\boldsymbol{\zeta}, \mathcal{L}_s)}}{4\pi(\rho(\mathbf{x}_0)\rho_0(\boldsymbol{\zeta})|\mathcal{R}_s(\boldsymbol{\zeta}, \mathcal{L}_s)|)^{1/2}} \times \left(\prod \mathcal{T}_{\ell_j}(\mathcal{L}_s) \right) \left(\begin{matrix} \tilde{\mathbf{v}}_s \\ \tilde{\mathbf{T}}_{sm} \end{matrix} \right) (\boldsymbol{\zeta}, \mathcal{L}_s) \hat{\mathbf{g}}^T(\mathbf{x}_0, \mathcal{L}_s) \quad (145)$$

with

$$\tilde{\mathbf{v}}_s(\boldsymbol{\zeta}, \mathcal{L}_s) = \hat{\mathbf{g}}_s + \sum_{l=1}^3 \mathcal{T}_{ls} \left| \frac{\rho_s \mathcal{R}_s}{\rho_r \mathcal{R}_{1l}} \right|^{1/2} \hat{\mathbf{g}}_{1l} \quad (146)$$

$$\tilde{\mathbf{T}}_{sm}(\boldsymbol{\zeta}, \mathcal{L}_s) = -\mathbf{Z}_{sm} \hat{\mathbf{g}}_s - \sum_{l=1}^3 \mathcal{T}_{ls} \left| \frac{\rho_s \mathcal{R}_s}{\rho_r \mathcal{R}_{1l}} \right|^{1/2} \mathbf{Z}_{1lm} \hat{\mathbf{g}}_{1l} \quad (147)$$

where in these expressions we have omitted the argument $(\boldsymbol{\zeta}, \mathcal{L}_s)$, have used the subscript notation for incident and reflected waves from Section 2.8, e.g., Eq. (94), and have used

the subscript s to indicate the source ray type. Note that the matrix impedances for each term in the tractions differ as the slowness vectors, $\mathbf{p}_s$ and $\mathbf{p}_{1l}$, differ. The ratio of the spreading functions for the incident and generated rays can be replaced by the inverse ratio of the normalization factors used in the eigenvectors (77) for the r/t coefficients [Eq. (94) is equivalent to Eq. (80)]. Again the product of coefficients is for interfaces between $\mathbf{x}_0$ and $\boldsymbol{\zeta}$ but not the interface at $\boldsymbol{\zeta}$. Expressions (146) and (147) contain the coefficients of the interface at $\boldsymbol{\zeta}$.

Combining the ray theory approximation for the wave from the source to the interface (145) with the free-space Green function (143), in the surface integral (142), we have

$$\mathbf{v}(\omega, \mathbf{x}; \mathbf{x}_0) = -i\omega \int e^{i\omega\theta(\mathbf{x}, \mathcal{L}_r, \mathcal{L}_s)} \underline{\mathbf{A}}(\boldsymbol{\zeta}, \mathcal{L}_r, \mathcal{L}_s) d\mathbf{s} \quad (148)$$

where

$$\theta(\boldsymbol{\zeta}, \mathcal{L}_r, \mathcal{L}_s) = T(\boldsymbol{\zeta}, \mathcal{L}_r) + T(\boldsymbol{\zeta}, \mathcal{L}_s) \quad (149)$$

$$\begin{aligned} \underline{\mathbf{A}}(\boldsymbol{\zeta}, \mathcal{L}_r, \mathcal{L}_s) = & -\frac{e^{-i(\pi/2)\text{sgn}(\omega)(\sigma(\boldsymbol{\zeta}, \mathcal{L}_r) + \sigma(\boldsymbol{\zeta}, \mathcal{L}_s))}}{16\pi^2(\rho(\mathbf{x})\rho(\mathbf{x}_0)\rho_s(\boldsymbol{\zeta})\rho_r(\boldsymbol{\zeta}))^{1/2}} \\ & \times \left(\prod \mathcal{T}_{lj}(\mathcal{L}_r) \right) \left(\prod \mathcal{T}_{lj}(\mathcal{L}_s) \right) \\ & \times \hat{\mathbf{g}}^T(\boldsymbol{\zeta}, \mathcal{L}_r) \left[\mathbf{Z}_m^T(\boldsymbol{\zeta}, \mathcal{L}_r) \tilde{\mathbf{V}}_s(\boldsymbol{\zeta}, \mathcal{L}_s) \right. \\ & \left. + \tilde{\mathbf{T}}_{sm}(\boldsymbol{\zeta}, \mathcal{L}_s) \right] \hat{n}_m \hat{\mathbf{g}}(\mathbf{x}, \mathcal{L}_r) \hat{\mathbf{g}}^T(\mathbf{x}, \mathcal{L}_s) \end{aligned} \quad (150)$$

For numerical purposes, it is straightforward to transform Eq. (148) into the time-domain:

$$\mathbf{v}(t, \mathbf{x}; \mathbf{x}_0) = \frac{d}{dt} \text{Re} \left[\Delta(t) * \int_{t=\theta} \underline{\mathbf{A}}(\boldsymbol{\zeta}, \mathcal{L}_r, \mathcal{L}_s) \frac{ds}{|\nabla_{\mathbf{s}} \theta(\boldsymbol{\zeta}, \mathcal{L}_r, \mathcal{L}_s)|} \right] \quad (151)$$

$$\simeq \frac{1}{2\Delta t} \frac{d}{dt} \text{Re} \left[\Delta(t) * \int_{t=\theta \pm \Delta t} \underline{\mathbf{A}}(\boldsymbol{\zeta}, \mathcal{L}_r, \mathcal{L}_s) ds \right] \quad (152)$$

where ds is the line element. The integral in the impulse response (151), is evaluated along lines on the surface where $t = \theta(\boldsymbol{\zeta}, \mathcal{L}_r, \mathcal{L}_s)$. The bandlimited result (152), which is in a form suitable for numerical evaluation, has surface integrals over strips defined by $t = \theta(\boldsymbol{\zeta}, \mathcal{L}_r, \mathcal{L}_s) \pm \Delta t$. If the surface is divided into triangular elements, where the ray results are known at the apexes, then exactly the same algorithm used for Maslov seismograms can be used to evaluate these surface integrals efficiently (Spencer *et al.*, 1997; Figure 5 and Appendix).

The surface integral (148) has stationary points [and (151) has corresponding singularities] when

$$\begin{aligned} \nabla_{\mathbf{s}} \theta(\boldsymbol{\zeta}, \mathcal{L}_r, \mathcal{L}_s) &= \nabla_{\perp} T(\boldsymbol{\zeta}, \mathcal{L}_r) + \nabla_{\perp} T(\boldsymbol{\zeta}, \mathcal{L}_s) \\ &= \mathbf{p}_{\perp}(\boldsymbol{\zeta}, \mathcal{L}_r) + \mathbf{p}_{\perp}(\boldsymbol{\zeta}, \mathcal{L}_s) = \mathbf{0} \end{aligned} \quad (153)$$

which corresponds to the Snell's law condition for a specular reflection [cf. Eq. (57)—remember that $\mathbf{p}(\boldsymbol{\zeta}, \mathcal{L}_r)$ is reversed

compared with the combined ray]. The appropriate reflected ray in Eqs. (146) and (147) will match the receiver ray at this point. Usually only this term is retained in the Kirchhoff integral and the other parts of the wavefield on the interface (146) and (147) are dropped. However, if they are retained, to first order they make no contribution to the integral. Let us consider the scattering term in $\underline{\mathbf{A}}$ (150), i.e.,

$$\begin{aligned} & -\hat{\mathbf{g}}^T(\boldsymbol{\zeta}, \mathcal{L}_r) \left[\mathbf{Z}_m^T(\boldsymbol{\zeta}, \mathcal{L}_r) \tilde{\mathbf{V}}_s(\boldsymbol{\zeta}, \mathcal{L}_s) + \tilde{\mathbf{T}}_{sm}(\boldsymbol{\zeta}, \mathcal{L}_s) \right] \hat{n}_m \\ &= \sum_{l=0}^3 \mathcal{T}_{ls}(\mathcal{L}_s) \hat{n}_m \left| \frac{\rho_s \mathcal{R}_s}{\rho_r \mathcal{R}_{1l}} \right|^{1/2} \hat{\mathbf{g}}^T(\boldsymbol{\zeta}, \mathcal{L}_r) [\mathbf{Z}_{1lm}(\boldsymbol{\zeta}, \mathcal{L}_s) \\ & \quad - \mathbf{Z}_{rm}^T(\boldsymbol{\zeta}, \mathcal{L}_r)] \hat{\mathbf{g}}_{il}(\boldsymbol{\zeta}, \mathcal{L}_s) \end{aligned} \quad (154)$$

$$\begin{aligned} &= \sum_{l=0}^3 \mathcal{T}_{ls}(\mathcal{L}_s) \left| \frac{\rho_s \mathcal{R}_s}{\rho_r \mathcal{R}_{1l}} \right|^{1/2} [\hat{n}_j p_m(\boldsymbol{\zeta}, \mathcal{L}_s)_{1l} \\ & \quad - \hat{n}_m p_j(\boldsymbol{\zeta}, \mathcal{L}_r)_r] \hat{\mathbf{g}}^T(\boldsymbol{\zeta}, \mathcal{L}_r) \mathbf{c}_{jm}(\boldsymbol{\zeta}) \hat{\mathbf{g}}_{il}(\boldsymbol{\zeta}, \mathcal{L}_s) \end{aligned} \quad (155)$$

using Eqs. (144), (146), and (147), where for brevity we have indicated the incident wave by $l=0$, i.e., subscript $1l \rightarrow s$ and $\mathcal{T}_{0s} = 1$. This expression (155) contains the directionality of the *obliquity factor*. At the saddle point defined by (153), when the appropriate reflection matches the receiver ray, the contribution to (155) from the other three terms (incident ray and two reflections) is zero using the orthogonality relationship in Eq. (79), and it reduces to

$$\begin{aligned} & -\hat{\mathbf{g}}^T(\boldsymbol{\zeta}, \mathcal{L}_r) \left[\mathbf{Z}_m^T(\boldsymbol{\zeta}, \mathcal{L}_r) \tilde{\mathbf{V}}_s(\boldsymbol{\zeta}, \mathcal{L}_s) + \tilde{\mathbf{T}}_{sm}(\boldsymbol{\zeta}, \mathcal{L}_s) \right] \hat{n}_m \\ &= 2\mathcal{T}_{rs}(\mathcal{L}_s) \mathbf{U}_{1r}^T \hat{\mathbf{n}} \left(\rho_s \rho_r \left| \frac{\mathcal{R}_s}{\mathcal{R}_{1r}} \right| \right)^{1/2} \end{aligned} \quad (156)$$

where we have let $l=r$ for the matching ray. $\mathcal{T}_{rs}(\mathcal{L}_s)$ is the reflection coefficient of the interface at $\boldsymbol{\zeta}$. The saddle point contribution can be evaluated using the stationary phase method (Bleistein, 1984, p. 88) and reduces to the ray theory result (93), where the saddle point values give

$$T(\mathbf{x}, \mathbf{x}_0) = \theta(\boldsymbol{\zeta}, \mathcal{L}_r, \mathcal{L}_s) = T(\boldsymbol{\zeta}, \mathcal{L}_r) + T(\boldsymbol{\zeta}, \mathcal{L}_s) \quad (157)$$

$$\sigma(\mathbf{x}, \mathbf{x}_0) = \sigma(\boldsymbol{\zeta}, \mathcal{L}_r) + \sigma(\boldsymbol{\zeta}, \mathcal{L}_s) + 1 - \frac{1}{2} \text{sgn}(\nabla_{\mathbf{s}}(\nabla_{\mathbf{s}} \theta)^T) \quad (158)$$

(Ursin and Tygel, 1997). Using the symmetries of the dynamic propagator (41), the factor $|\mathcal{R}_r \mathcal{R}_{1r}|$ can be related to $|\mathcal{R}|$ for the complete ray using $\|\nabla_{\mathbf{s}}(\nabla_{\mathbf{s}} \theta)^T\|$ (Coates and Chapman, 1990a; Ursin and Tygel, 1997).

4.3 Quasi-Isotropic Ray Theory

In addition to the degeneracy that always occurs in isotropic media, degeneracy may occur in anisotropic media. In certain directions, the quasi-shear (qS) waves degenerate and their

velocities are equal. In these directions, degenerate theory must be used.

Near these degenerate directions, and in the case of weak, heterogeneous anisotropy, in all directions, standard anisotropic ray theory breaks down as the qS velocities are similar (H_N small) and the additional terms [Eq. (25)] blow up (errors in asymptotic ray theory are bounded by the next term). In homogeneous media, the two qS waves propagate independently as they do in anisotropic media when the velocities are significantly different (making the additional term small). They interact when these conditions fail as the time separation of the two waves is small compared with the pulse period. This occurs when $L \Delta U / U^2 < 2\pi/\omega$, where ΔU is the difference in qS velocities and L is a characteristic length of the heterogeneities. If we use anisotropic ray theory in weakly anisotropic media or near degeneracies, and assume the qS waves propagate independently, then absurd results can be obtained. Rapid changes in polarization are predicted for each independent ray that are clearly not allowed physically.

To use ray methods at or near degeneracies and in weakly anisotropic media, we use a quasi-isotropic (QI) ray theory introduced by Pšenčík (1998) using a method by Kravtsov and Orlov (1990, p. 233). The effects of anisotropy and differences in the S velocities are modeled as perturbations to the isotropic solution by treating the anisotropic part of the model as another small parameter, in addition to $1/\omega$, in the asymptotic expansion.

We factor the elastic parameters into isotropic and anisotropic parts, e.g.,

$$c_{ijkl} = c_{ijkl}^0 + \Delta c_{ijkl} \quad (159)$$

where c_{ijkl}^0 is isotropic, i.e., like Eq. (98),

$$c_{ijkl}^0 = \lambda \delta_{ij} \delta_{kl} + \mu (\delta_{ik} \delta_{jl} + \delta_{il} \delta_{jk}) \quad (160)$$

We assume that Δc_{ijkl} is small and of order $1/\omega$. Substituting Eq. (159) in the constitutive equation (2), and using the same ray ansätze [Eq. (3)], we obtain a revised equation (6):

$$\begin{aligned} \mathbf{c}_{jk}^0 \frac{\partial \mathbf{V}^{(m-1)}}{\partial x_k} - i\omega \Delta \mathbf{c}_{jk} \frac{\partial \mathbf{V}^{(m-2)}}{\partial x_k} \\ = \mathbf{T}_j^{(m)} + p_k \mathbf{c}_{jk}^0 \mathbf{V}^{(m)} - i\omega p_k \Delta \mathbf{c}_{jk} \mathbf{V}^{(m-1)} \end{aligned} \quad (161)$$

Note that the new terms in this equation are frequency dependent and have been included as $O(\omega \Delta c_{ijkl}) \sim 1$. Equation (5) remains valid, and as before $\mathbf{T}_j^{(m)}$ can be eliminated between Eqs. (5) and (161) to obtain a revised version of Eq. (9),

$$\begin{aligned} \mathbf{N}^0(\mathbf{V}^{(m)}) - \bar{\mathbf{M}}^0(\mathbf{V}^{(m-1)}, \mathbf{T}_j^{(m-1)}) \\ = i\omega p_j \Delta \mathbf{c}_{jk} \left(p_k \mathbf{V}^{(m-1)} - \frac{\partial \mathbf{V}^{(m-2)}}{\partial x_k} \right) \end{aligned} \quad (162)$$

the operators $\mathbf{N}^0$ and $\bar{\mathbf{M}}^0$ being in the isotropic model.

4.3.1 The Quasi-Isotropic Eikonal

The $m=0$ terms are as before for the isotropic part of the model, c_{ijkl}^0 , i.e., Eq. (162) reduces to Eq. (15) when $m=0$. Thus the rays are traced in the isotropic part of the model (see Section 3.1). The P ray is longitudinal, i.e., $\hat{\mathbf{g}}_3 = \alpha \mathbf{p}$. The S rays are degenerate and the polarizations are in the plane perpendicular to the ray.

4.3.2 The Quasi-Isotropic Transport Equation

Letting $m=1$ in expression (162) and proceeding as before, the transport equation (36) is modified to

$$\nabla \cdot \mathbf{N} = -i\omega \mathbf{V}^{(0)\text{T}} p_j p_k \Delta \mathbf{c}_{jk} \mathbf{V}^{(0)} \quad (163)$$

For future use, we define

$$B_{\mu\nu} = \frac{\hat{p}_j \hat{p}_k \hat{\mathbf{g}}_\mu^{\text{T}} \Delta \mathbf{c}_{jk} \hat{\mathbf{g}}_\nu}{\rho} \quad (164)$$

P Quasi-Isotropic Rays. As the isotropic eikonal applies, the polarization is still longitudinal, i.e., $\mathbf{V}^{(0)} = V_3^{(0)} \hat{\mathbf{g}}_3$ where $\hat{\mathbf{g}}_3 = \alpha \mathbf{p}$.

For P waves, (163) reduces to [cf. Eq. (30)]

$$\frac{d}{dT} \ln(\rho V_3^{(0)2}) = -\nabla \cdot \mathbf{U} - i\omega \frac{B_{33}}{\alpha^2} \quad (165)$$

where B_{33} is defined in Eq. (164), Combining with Eq. (32),

$$\frac{d}{dT} \ln(\rho u V_3^{(0)2} J) = -i\omega \frac{B_{33}}{\alpha^2} \quad (166)$$

and the solution is

$$\begin{aligned} V_3^{(0)} &= \frac{\text{constant}}{\sqrt{\rho u |J|}} \exp(i\omega \Delta T_3), \quad \text{where} \\ \Delta T_3 &= - \int_{\mathcal{L}_n} \frac{B_{33}}{2\alpha^3} ds \end{aligned} \quad (167)$$

is the travel time shift due to the anisotropic perturbation (Červený, 1982; Hanyga, 1982b; Červený and Jech, 1982).

The additional terms are evaluated as before, Eq. (25), including the extra QI term

$$V_N^{(1)} = \frac{1}{2\rho H_N} \hat{\mathbf{g}}_N^{\text{T}} \left(\bar{\mathbf{M}}(\mathbf{V}^{(0)}, \mathbf{T}_j^{(0)}) + i\omega p_j p_k \Delta \mathbf{c}_{jk} \mathbf{V}^{(0)} \right) \quad (168)$$

Specializing to the quasi-isotropic P wave ($\mathbf{V}^{(0)} = V_3^{(0)} \hat{\mathbf{g}}_3$), we obtain the isotropic terms (118) plus additional QI terms:

$$\begin{aligned} V_\nu^{(1)} &= -\hat{\mathbf{g}}_\nu^{\text{T}} \left(\alpha \frac{\partial V_3^{(0)}}{\partial g_\nu} + \frac{V_3^{(0)}}{\alpha^2 - \beta^2} [(\alpha^2 - \beta^2) \nabla \alpha - 4\alpha\beta \nabla \beta \right. \\ &\quad \left. + \alpha(\alpha^2 - 2\beta^2) \nabla(\ln \rho)] \right) + \frac{i\omega \alpha^2 \hat{\mathbf{g}}_\nu^{\text{T}}}{\rho(\beta^2 - \alpha^2)} \\ &\quad \times \left(p_j (\mathbf{c}_{jk}^0 + \mathbf{c}_{kj}^0) \mathbf{V}^{(0)} \frac{\partial(\Delta T_3)}{\partial x_k} + p_j p_k \Delta \mathbf{c}_{jk} \mathbf{V}^{(0)} \right) \end{aligned} \quad (169)$$

Using Eqs. (106) and (107), and definition (164), we obtain

$$V_\nu^{(1)} = -\hat{\mathbf{g}}_\nu^T \left(\alpha \frac{\partial V_3^{(0)}}{\partial g_\nu} + \frac{V_3^{(0)}}{\alpha^2 - \beta^2} [(\alpha^2 - \beta^2) \nabla \alpha - 4\alpha\beta \nabla \beta + \alpha(\alpha^2 - 2\beta^2) \nabla(\ln \rho)] \right) - i\omega V_3^{(0)} \left(\alpha \frac{\partial(\Delta T_3)}{\partial g_\nu} + \frac{B_{\nu 3}}{\alpha^2 - \beta^2} \right) \quad (170)$$

The two extra QI terms were described by Pšenčík (1998). They are proportional to frequency, so overall their contribution is independent of frequency (and the perturbed polarization due to anisotropy remains linear in contrast to additional terms due to heterogeneity). The first QI term corrects the polarization due to the perturbation in $\mathbf{p}$ from the anisotropy. The second term corrects the polarization for deviations from the slowness vector in the anisotropic medium. It has also been obtained using the perturbation method (Jech and Pšenčík, 1989; Pšenčík and Gajewski, 1998).

S Quasi-Isotropic Rays. Now the polarization is degenerate. The shear polarization can be written as a combination of any two orthogonal vectors in the transverse plane. Various choices suggest themselves, e.g., the isotropic shear polarizations, $\hat{\mathbf{g}}_\nu^0$, or the polarizations in the anisotropic medium, themselves perhaps estimated by perturbation theory. Pšenčík (1998) has considered both cases and argues that the former case is easier. In this, the polarizations are easily calculated using Eq. (117) and in the QI limit, never generate strong coupling between the solutions. The latter choice requires that the anisotropic polarizations be found and, as they may vary rapidly, will generate strong coupling between the two solutions. The second case is equivalent to that of Coates and Chapman (1990b), who investigated this coupling between qS waves. A final possibility is to use the normal and binormal vectors as a basis, but given that the isotropic polarizations, $\hat{\mathbf{g}}_\nu^0$, are known, this offers no advantages. We therefore follow Pšenčík (1998).

Thus, we write

$$\mathbf{V}^{(0)} = V_\nu^{(0)} \hat{\mathbf{g}}_\nu^0 \quad (171)$$

where $\hat{\mathbf{g}}_\nu^0$ are found by solving Eq. (117) in the isotropic part of the model. Premultiplying Eq. (162) by $\hat{\mathbf{g}}_\eta^T$, we modify Eq. (111) to

$$\hat{\mathbf{g}}_\eta^T \mathbf{M}(V_\nu^{(0)} \hat{\mathbf{g}}_\nu^0) = -\frac{i\omega\rho}{\beta^2} B_{\eta\nu} V_\nu^{(0)} \quad (172)$$

Then Eq. (112) is modified to

$$\delta_{\nu\eta} (2\mu \mathbf{p} \cdot \nabla V_\nu^{(0)} + \mathbf{V}_\nu^{(0)} \mathbf{p} \cdot \nabla \mu + \mu V_\nu^{(0)} \nabla \cdot \mathbf{p}) + 2\rho V_\nu^{(0)} \hat{\mathbf{g}}_\eta^{0T} \frac{d\hat{\mathbf{g}}_\nu^0}{dT} = -\frac{i\omega\rho}{\beta^2} B_{\eta\nu} V_\nu^{(0)} \quad (173)$$

As we are using the isotropic shear polarizations, the last term on the LHS is zero [Eq. (117)], and this equation simplifies to

$$\frac{1}{V_\eta^{(0)}} \nabla \cdot (\rho \beta^2 V_\eta^{(0)} \mathbf{p}) = -\frac{i\omega\rho}{\beta^2} B_{\eta\nu} V_\nu^{(0)} \quad (174)$$

(no summation over η). We define new amplitude coefficients with the behavior (35) removed,

$$\tilde{V}_\nu^{(0)} = V_\nu^{(0)} \sqrt{\rho\beta|J|} \quad (175)$$

and Eq. (174) reduces to

$$\frac{d\tilde{\mathbf{V}}^{(0)}}{dT} = -\frac{i\omega}{2\beta^2} \mathbf{B} \tilde{\mathbf{V}}^{(0)} \quad (176)$$

where we have used Eq. (32). $\tilde{\mathbf{V}}^{(0)}$ is the 2-vector with components $\tilde{V}_\nu^{(0)}$ and $\mathbf{B}$ is the 2×2 matrix with components $B_{\eta\nu}$. This equation (176) models the frequency-dependent coupling between the isotropic shear polarizations. In the isotropic limit, the RHS is zero and $\tilde{\mathbf{V}}^{(0)}$ is constant, i.e., the components are independent in an isotropic model.

In order to analyze the solution further, we need the eigenvalues of the matrix $\mathbf{B}$. These are

$$b_\nu = \frac{1}{2}(B_{11} + B_{22} \mp B), \quad \text{where} \quad B = \left[(B_{11} - B_{22})^2 + 4B_{12}^2 \right]^{1/2} \quad (177)$$

(as before, let us choose $\nu=1$ for the slower qS ray which corresponds to the negative sign, and $\nu=2$ with the positive sign—this differs from Pšenčík (1998) as we have ordered the solutions with increasing velocity). Solutions of Eq. (176) can be considered in two regimes, corresponding to low and high frequencies. When the elements of $\mathbf{B}$ are small (in the sense that $\omega T b / \beta^2 \ll 1$, which is equivalent to the QI condition given above), $\tilde{\mathbf{V}}^{(0)}$ varies slowly and Eq. (176) is relatively easy to solve numerically. Any of the standard techniques for finding a propagator can be used. Assuming $\mathbf{B}$ can be approximated as piecewise constant, the propagator is easily found from the eigenvector matrix

$$\Phi = \begin{pmatrix} \cos \phi & -\sin \phi \\ \sin \phi & \cos \phi \end{pmatrix} \quad (178)$$

(the first column corresponds to b_1 and the second to b_2) where the rotation angle, ϕ , is found from

$$\tan 2\phi = \frac{2B_{12}}{B_{22} - B_{11}} \quad (179)$$

The propagator for a constant $\mathbf{B}$ interval T to $T + \Delta T$ is then

$$\mathcal{V}(T + \Delta T, T) = \Phi \Lambda(T + \Delta T, T) \Phi^{-1} \quad (180)$$

where

$$\mathbf{A}(T + \Delta T, T) = \begin{pmatrix} e^{i\omega\Delta T_1} & 0 \\ 0 & e^{i\omega\Delta T_2} \end{pmatrix} \quad \text{with} \quad \Delta T_\nu = - \int_T^{T+\Delta T} \frac{b_\nu}{2\beta^2} dT \quad (181)$$

The angle ϕ is the rotation of the anisotropic qS polarizations, and ΔT_ν are the travel time perturbations, relative to the isotropic results (by degenerate perturbation theory—Jech and Pšenčík, 1989). Expanding Eq. (180) and inverting the Fourier transform, we can increment $\tilde{\mathbf{V}}^{(0)}(t, T)$ using

$$\begin{aligned} \tilde{\mathbf{V}}^{(0)}(t, T + \Delta T) &= \begin{pmatrix} \cos^2 \phi & \cos \phi \sin \phi \\ \cos \phi \sin \phi & \sin^2 \phi \end{pmatrix} \tilde{\mathbf{V}}^{(0)}(t + \Delta T_1, T) \\ &+ \begin{pmatrix} \sin^2 \phi & -\cos \phi \sin \phi \\ -\cos \phi \sin \phi & \cos^2 \phi \end{pmatrix} \tilde{\mathbf{V}}^{(0)}(t + \Delta T_2, T) \end{aligned} \quad (182)$$

The time-domain solution is attractive as usually the response is compact in the time domain.

When the QI condition is not satisfied, i.e., in the high-frequency limit except at degeneracies, we would expect the quasi-shear rays to propagate independently (Section 2). Expanding the solution in terms of anisotropic rays,

$$\tilde{\mathbf{V}}^{(0)} = \Phi \mathbf{A}(T, T_0) \bar{\mathbf{V}}^{(0)} \quad (183)$$

the differential equation (176) becomes

$$\frac{d\bar{\mathbf{V}}^{(0)}}{dT} = - \frac{d\phi}{dT} \mathbf{A}^{-1} \mathbf{I}_1 \mathbf{A} \bar{\mathbf{V}}^{(0)} \quad (184)$$

or

$$\frac{d\bar{\mathbf{V}}^{(0)}}{d\phi} = \begin{pmatrix} 0 & -e^{-i\omega\Delta T_{12}} \\ e^{-i\omega\Delta T_{21}} & 0 \end{pmatrix} \bar{\mathbf{V}}^{(0)} \quad (185)$$

where

$$\begin{aligned} \Delta T_{12} = -\Delta T_{21} = \Delta T_1 - \Delta T_2 &= - \int_{T_0}^T \frac{b_1 - b_2}{2\beta^2} dT \\ &= \int_{T_0}^T \frac{B}{2\beta^2} dT \end{aligned} \quad (186)$$

Assuming ΔT_{12} can be approximated as constant, the propagator for Eq. (185) is

$$\begin{aligned} \bar{\mathbf{V}}^{(0)}(\omega, T + \Delta T) &= \begin{pmatrix} \cos \Delta\phi & -e^{-i\omega\Delta T_{12}} \sin \Delta\phi \\ e^{-i\omega\Delta T_{21}} \sin \Delta\phi & \cos \Delta\phi \end{pmatrix} \bar{\mathbf{V}}^{(0)}(\omega, T) \end{aligned} \quad (187)$$

whatever the size of $\Delta\phi$, i.e., even if $d\phi/dT$ is large, such as near a singularity. Again the time-domain solution

$$\begin{aligned} \bar{V}_1^{(0)}(t, T + \Delta T) &= \cos \Delta\phi \bar{V}_1^{(0)}(t, T) - \sin \Delta\phi \bar{V}_2^{(0)}(t - \Delta T_{12}, T) \\ \bar{V}_2^{(0)}(t, T + \Delta T) &= \sin \Delta\phi \bar{V}_1^{(0)}(t - \Delta T_{21}, T) + \cos \Delta\phi \bar{V}_2^{(0)}(t, T) \end{aligned} \quad (188)$$

is attractive. This is exactly equivalent to the solution obtained by Coates and Chapman (1990b) by a different technique.

Finally, we need the first-order additional term for shear waves. Equation (119) is modified to include the QI term

$$\begin{aligned} V_3^{(1)} &= \hat{\mathbf{g}}_3^T \left[\beta \frac{\partial V_\nu^{(0)}}{\partial g_\nu} + \frac{V_\nu^{(0)}}{\alpha^2 - \beta^2} \left((\alpha^2 + 3\beta^2) \nabla \beta + \beta^3 \nabla (\ln \rho) \right) \right] \\ &- i\omega V_\nu^{(0)} \frac{B_{3\nu}}{\alpha^2 - \beta^2} \end{aligned} \quad (189)$$

As before, overall the QI term is independent of frequency and describes the correction to the shear polarization, in agreement with degenerate perturbation theory (Jech and Pšenčík, 1989).

Acknowledgments

Most of this chapter was written while the author was visiting Queen's University, Kingston, Canada in 1998. He thanks Professor Colin Thomson for arranging the visit and for many useful discussions, and Schlumberger Cambridge Research for permitting the visit and publication of this chapter. Reviewers Professor Vlastislav Červený and Leo Eisner provided many useful suggestions.

Appendix: Triangular Integration

The bandlimited Maslov and Kirchhoff seismograms (Sections 4.1 and 4.2) both reduce to area integrals [Eqs. (141) and (152)]. If the corresponding domain, ray tubes or interface, is triangulated (Figs. 5 and 6), these integrals can be efficiently evaluated using an algorithm described in Spencer *et al.* (1997).

Consider a ray tube (triangle) ABC , with phases θ_A , etc. and amplitudes $\mathbf{A}_A$, etc. Let us assume that the phases are ordered $\theta_A < t < \theta_B < \theta_C$. The line DD' is where $t = \theta$ and B' is where $\theta = \theta_B$ on the side AC . The area of the triangle ADD' is

$$\Delta_{ADD'} = \frac{(t - \theta_A)^2}{(\theta_B - \theta_A)^2} \Delta_{ABB'} \quad (190)$$

FIGURE 6 A triangular element. The phase at B' is the same as B . For a phase between A and B , e.g., D , the triangle ADD' is similar to ABB' and its area is easily calculated.

To obtain the integral of $\mathbf{A}$ over this triangle with linear interpolation, we just need the mean of the amplitude at A , $\mathbf{A}_A$, and at D and D' , i.e.,

$$\mathbf{A}_D = \mathbf{A}_A + \frac{\mathbf{A}_B - \mathbf{A}_A}{\theta_B - \theta_A} (t - \theta_A) \quad (191)$$

$$\mathbf{A}_{D'} = \mathbf{A}_A + \frac{\mathbf{A}_C - \mathbf{A}_A}{\theta_C - \theta_A} (t - \theta_A) \quad (192)$$

Thus,

$$\begin{aligned} \iint_{\mathbf{q}_i}^{t=0} \mathbf{A} d\mathbf{q} &= \left[\mathbf{A}_A + \frac{1}{3} \left(\frac{\mathbf{A}_B - \mathbf{A}_A}{\theta_B - \theta_A} + \frac{\mathbf{A}_C - \mathbf{A}_A}{\theta_C - \theta_A} \right) (t - \theta_A) \right] \Delta_{ADD'} \\ &= \left[\mathbf{A}_A + \frac{1}{3} \left(\frac{\mathbf{A}_B - \mathbf{A}_A}{\theta_B - \theta_A} + \frac{\mathbf{A}_C - \mathbf{A}_A}{\theta_C - \theta_A} \right) (t - \theta_A) \right] \\ &\quad \times \frac{(t - \theta_A)^2}{(\theta_B - \theta_A)^2} \Delta_{ABB'} \end{aligned} \quad (193)$$

where $\mathbf{q}$ is either the ray parameter or interface variable. Similar results hold for $t > \theta_B$. Repeating at intervals of Δt , results for strips are obtained by subtraction.

Normal Modes of the Earth and Planets

Philippe Lognonné and Eric Clévéde
Institut de Physique du Globe de Paris, France

1. Introduction and Historical Key Dates

During almost a century, and up to 1960, normal modes were only theoretical concepts. Normal modes of the Earth were first described by Lord Kelvin (Thomson, 1863a,b) with a computation of the lowest fundamental spheroidal mode ${}_0S_2$ frequency for a homogeneous Earth model, either fluid or rigid. This early attempt was followed by a complete description of the normal modes of a spherical nonrotating elastic isotropic (SNREI) Earth in the early works of Rayleigh (1894, 1906) and Love (1911). The first computations of normal mode frequencies for realistic models of the Earth (at that time obtained from body wave arrival time data) were performed independently by Jobert (1956, 1957), Pekeris and Jarosh (1958), and Takeuchi (1959), as well as by Alterman *et al.* (1959) with a more complete calculation of eigenfrequencies and eigenmodes, and the search for normal mode signatures started in the very late 1950s (Benioff *et al.*, 1959).

The theory and the deployment in the late 1950s of the first real long-period sensors, such as strainmeters, tiltmeters, or gravimeters, were therefore just in time for the Chile 1960 earthquake. The analyses of records performed by Benioff *et al.* (1961), Ness *et al.* (1961), Alsop *et al.* (1961), Bolt and Marussi (1962), and Connes *et al.* (1962) showed an excellent fit with the theoretical frequencies, as well as splitting related to the rotation of the Earth (Backus and Gilbert, 1961; Pekeris *et al.*, 1961). These first early observations were just the starting point, followed later by a continuous increase of the number of observations, from about 250 modes (Derr, 1969a; Dziewonski and Gilbert, 1972, 1973) to more than 1000 modes (Gilbert and Dziewonski, 1975; Dziewonski and Anderson, 1981). The inversion of the two last sets of data produced, respectively, the 1066 A-B and PREM models, still today used often as the reference model for normal mode and

internal structure studies. These two models were also the first seismic models to measure directly the density profile of the Earth, through the sensitivity of normal modes to gravitation. Only a few new modes were later discovered by the analysis of subsequent earthquakes, such as the lowest toroidal mode, ${}_0T_2$, for which the first observation was made only after the 1989 Macquarie Rise earthquake (Widmer *et al.*, 1992b), almost 30 years later than ${}_0S_2$.

From a theoretical point of view and after the pioneering work of Backus and Gilbert (1961), most of the attention after 1970 was given to the effect of elastic lateral variations and ellipticity. Perturbation theory appeared very rapidly as a powerful tool for the treatment first of the Earth rotation and ellipticity (Dahlen, 1968) and then of the lateral variations in the isolated multiplet case by Zharkov and Lyubimov (1970a,b) and Madariaga (1972). Later, refined perturbation theories were used: quasi-degenerate theory for the rotation and ellipticity (Dahlen, 1969) or for lateral variations (Woodhouse, 1980), and higher-order perturbation theory (Lognonné and Romanowicz, 1990a; Park, 1990b). The development of computers also allowed the brute-force resolution of the problem with variational methods (Park and Gilbert, 1986; Hara *et al.*, 1991, 1993). In parallel with these theoretical and numerical studies, observations and inversions were performed to constrain the lateral variations of the Earth with early works of Jordan (1978) and Silver and Jordan (1981), the latter leading to the discovery of the elastic degree-two pattern of the Earth's mantle (Masters *et al.*, 1982) and of the anomalous splitting of some modes depicting a large sensitivity to the core (Masters and Gilbert, 1981). However, after almost two decades of discussions, a complete explanation of all anomalous modes and of body wave travel times in the core is still lacking. Normal modes, as intermediate functions in the computation of seismograms, were also used for the first 3D tomographic model of Woodhouse and Dziewonski (1984).

The late 1980s and 1990s saw the first observation of attenuation lateral variation (e.g., Romanowicz, 1990, 1994; Roult *et al.*, 1990) and the final refinements in the theory of normal modes. The theoretical framework for a nonhydrostatic prestressed Earth was completed by Woodhouse and Dahlen (1978) and Valette (1986), but the signature of prestress in seismic data has not yet been reported. Theory taking into account the attenuation was also developed, first in a non-rotating Earth (Lognonné, 1989), and then in a rotating anelastic Earth (Lognonné, 1991), in the latter case correcting and completing earlier work of Dahlen (1981) and Park and Gilbert (1986).

The last and most recent step was performed in 1998, with the discovery of the permanent excitation of the normal modes of the Earth. Despite an early suggestion of Benioff *et al.* (1959), normal modes were always sought only after strong earthquakes. Nawa *et al.* (1998), Suda *et al.* (1998), and Kobayashi and Nishida (1998) showed that normal modes were in fact permanently excited, at the level of the nanogal ($10^{-11} \text{ m sec}^{-2}$), too small for their observation on a single record but sufficiently enhanced by stacking of at least one year's signals.

The aim of this chapter is to provide an overview of the theory of normal modes and of observations and inversions of normal modes performed since 1961. A much more detailed normal mode description can be found in Dahlen and Tromp (1998). The final results of these normal mode observations, i.e., the tomographic models of the Earth, are reviewed by Romanowicz (1991) and Ritzwoller and Lavelle (1995). Despite the fact that the Earth is the only telluric planet where normal modes have been observed, Lognonné *et al.* (1996) and Kobayashi and Nishida (1998) have shown that they may be observed on Mars and even possibly on Venus. See Lognonné and Mosser (1993) for a review of the planetary seismology and normal modes of the telluric and giant planets.

After description of the gravito-elastic equation, the normal modes of a SNREI model are briefly described. Numerical codes for the computation of these SNREI modes are provided on the attached Handbook CD, by courtesy of G. Masters. The perturbation theory for the modeling of the asphericity of the Earth is then presented, as well as the method of normal mode summation, which allows use of the aspherical modes for the computation of seismograms in a complex Earth. This chapter therefore describes the theory necessary for the numerical computation of the normal modes of a rotating, aspherical, anelastic, and anisotropic Earth. The software for the computation of the aspherical, anelastic, and anisotropic normal modes and seismograms is provided on the attached Handbook CD. See Chapter 85.16 by Clévéde and Lognonné for a summary, as well as a more detailed software manual on the attached Handbook CD. This software will provide the user with a tool for the computation of normal modes and seismograms in such a complex Earth.

2. The Gravito-Elastic Equation of Normal Modes in a Linear Aspherical, Anisotropic, and Anelastic and Rotating Earth

2.1 General Properties

Let us consider a general model of the Earth or another planet, including if necessary an ocean and an atmosphere, and let us suppose that all equations are expressed in the inertial frame, rotating with the angular velocity Ω . In the state of equilibrium, the prestress (or static pressure for fluid parts) is compensated by the gravity, the centrifugal force, as well as the Reynolds stress and thermal stress associated with convection and temperature gradient. We will focus on a hydrostatic prestressed Earth, where only gravity and centrifugal force are significant, which is used in most if not all data analysis. The general case can, however, be found in Dahlen and Tromp (1998), following works of Dahlen (1972, 1973), Woodhouse and Dahlen (1978), Valette (1986), and Vermeersen and Vlaar (1991), and must be used for attempts related to the search for the prestress deviatoric in the Earth.

In the state of equilibrium, the static stress of the Earth $\mathbf{T}_0$ at radius point $\mathbf{r}$ follows

$$\nabla \cdot \mathbf{T}_0 + \rho_0(\mathbf{g}_0 - \Omega \times (\Omega \times \mathbf{r})) = 0 \quad (1)$$

where ∇ is the derivative operator, $\mathbf{g}_0$ is the gravity of the Earth, and ρ_0 the density, both at equilibrium. We have added here the inertial force related to the rotation of the Earth frame, with an instantaneous rotation vector Ω . Let us now assume that the Earth is vibrating, as the result of some excitation. Denote by ρ the density in the nonequilibrium state and assume that, at time t , a particle initially at position $\mathbf{r}$ will then be at

$$\mathbf{r}'(t) = \mathbf{r} + \mathbf{u}(\mathbf{r}, t) \quad (2)$$

The principle of mechanics, expressed at the point $\mathbf{r}'$ can be written as

$$\rho \frac{d\mathbf{v}}{dt} = \nabla \cdot \mathbf{T} + \rho(\mathbf{g} - \Omega \times (\Omega \times \mathbf{r}')) - 2\rho\Omega \times \mathbf{v} \quad (3)$$

where $\mathbf{T}$, $\mathbf{g}$, and $\mathbf{v}$ are the stress tensor, gravity field, and particle velocity, all expressed at the position $\mathbf{r}'$ changing with time, and therefore in an Eulerian point of reference. Note that discontinuities of the Earth model will also be deformed with time. The Eulerian density and gravity can be expressed easily by considering a virtual time during which all deformations take place and has to follow the principle of mass conservation. Therefore, to first order,

$$\rho - \rho_0 + \text{div}(\rho_0 \mathbf{u}) = 0 \quad (4)$$

These density variations are affecting the gravity field of the planet with potential Φ , such that $\mathbf{g} = -\nabla\Phi$ has to be solution of

$$\nabla^2\Phi = 4\pi\mathcal{G}\rho \quad (5)$$

where $\mathcal{G}$ is the gravitational constant. From Eq. (4), this gravity field can therefore be decomposed into the equilibrium gravity field and a perturbation, related to a potential Φ_1 , called the redistribution potential, and such that $\mathbf{g} = \mathbf{g}_0 - \nabla\Phi_1$ with

$$\nabla^2\Phi_1 = -4\pi\mathcal{G}\text{div}(\rho_0\mathbf{u}) \quad (6)$$

We now have to obtain the expression of the Eulerian stress at $\mathbf{r}'$. This stress can be defined as the superposition of a transported stress and of a second term, related to stresses due to compression and shear acting on the media:

$$\begin{aligned} \mathbf{T}(\mathbf{r}') &= \mathbf{T}_0(\mathbf{r}' - \mathbf{u}(\mathbf{r}, t)) + \delta\mathbf{T}_{\text{elastic}}(\mathbf{r}, t) \\ &= \mathbf{T}_0(\mathbf{r}') - \mathbf{u} \cdot \nabla\mathbf{T}_0 + \delta\mathbf{T}_{\text{elastic}} \end{aligned} \quad (7)$$

which can be simplified in the hydrostatic case by replacing $\mathbf{T}_0$ by $-p_0\mathbf{I}$, where p_0 is the static pressure and $\mathbf{I}$ is the identity tensor. The second part is related to elastic or anelastic stresses. In the linear assumption, valid for the typical amplitudes of normal modes, we have for an elastic and linear model,

$$\delta T_{\text{elastic}}^{ij}(\mathbf{r}, t) = C^{ijkl} D_k u_l(\mathbf{r}, t) \quad (8)$$

where C^{ijkl} is the elastic tensor, and D_k the derivative operator along direction k , while, for anelastic and linear models, we have instead a generalization in terms of convolution:

$$\delta T_{\text{anelastic}}^{ij}(\mathbf{r}, t) = \int_0^{+\infty} C^{ijkl}(\tau) D_k u_l(\mathbf{r}, t - \tau) d\tau \quad (9)$$

In general, the tensor has 21 independent coefficients in the triclinic case and is symmetric, obeying $C^{ijkl} = C^{jilk} = C^{klij} = C^{iljk}$. In the isotropic case, we have two coefficients, and the tensor is such that

$$C^{ijkl} = (\kappa - \frac{2}{3}\mu)g^{ij}g^{kl} + \mu(g^{ik}g^{jl} + g^{il}g^{jk}) \quad (10)$$

where κ and μ are the bulk and shear modulus respectively, and where g^{ij} is the metric tensor of the projection basis. For a cartesian basis, it is equal to the Kronecker tensor, i.e., to 1 for $i = j$ and to 0 for other terms. For fluids, μ cancels.

2.2 Boundary Conditions

In the Eulerian description, boundaries are moving with time, as well as the normal to these surfaces. At solid/solid interfaces, the displacement is continuous as soon as the boundaries are welded. For liquid/solid or liquid/liquid boundaries, only the displacement perpendicular to the surface is continuous if no cavity at the surface is expected to occur (note here that the viscosity of ocean, atmosphere, and outer core is sufficiently small to be neglected in all the boundary conditions, for any frequency used in seismology).

Let us now focus on the stress continuity relations. A surface element, initially described with a surface element $d\Sigma_0$ and

normal vector $\mathbf{n}_0$ is therefore deformed and associated with a new surface $d\Sigma$ and a new normal vector $\mathbf{n}$. Assuming that the surface has no mass, we get the general continuity relation:

$$\mathbf{n}^+ \cdot \mathbf{T}^+ d\Sigma^+ = \mathbf{n}^- \cdot \mathbf{T}^- d\Sigma^- \quad (11)$$

where $\mathbf{T}$ is the stress expressed at position $\mathbf{r}'$, with expressions estimated above the surface for index $+$ and below it for index $-$. Both the normal vector and the surface element can be expressed by considering a local basis moving with the deformation and therefore associated with position $\mathbf{r}'$. By differentiating Eq. (2), we get

$$dX^i = (g_j^i + D_j u^i) dX^j = F_j^i dX^j \quad (12)$$

where X^i are the components of $\mathbf{r}'$, D_j are the j component of the derivative operator and F_j^i is the matrix associated with the coordinate change. The three rows of $\mathbf{F}^{-1}$ give the basis vectors, and for the normal vector we then get

$$\mathbf{n} = \mathbf{n}_0 - \nabla_\Sigma \mathbf{u}(\mathbf{n}_0) \quad (13)$$

where Σ denotes the tangential derivation. In the same way, it is possible to define the surface change, and we have

$$d\Sigma = d\Sigma_0(1 + \nabla_\Sigma \cdot \mathbf{u}) \quad (14)$$

From these two equations, and the expression (7) for the stress, we finally get the continuity relation of stresses, as shown in Table 1 for the hydrostatic case. The surface of the Earth model can be considered in different ways. The most common is a free surface at the base of the atmosphere, which leads to neglect of the seismic energy lost by acoustic conversion in the atmosphere of the Earth. This is clearly not valid when the seismic source is in the atmosphere, as for an atmospheric eruption or the permanent excitation of normal modes. In that case, a radiating surface at the top of the atmosphere is more adequate, as shown by Lognonné *et al.* (1998).

2.3 The Elastodynamic Equation of Normal Modes

The elastodynamic equation can now be detailed. Starting from Eq. (3) expressed at the position $\mathbf{r}'$, neglecting the advection term in the time derivation, and subtracting Eq. (1), we finally get

$$\begin{aligned} \rho_0(\partial_t^2 \mathbf{u} + 2\boldsymbol{\Omega} \times \partial_t \mathbf{u}) &= \nabla \cdot (\delta\mathbf{T}_{\text{elastic}} - \mathbf{u} \cdot \nabla\mathbf{T}_0) \\ &\quad - \text{div}(\rho_0\mathbf{u})\mathbf{g}_0' - \rho_0\nabla\Phi_1 \end{aligned} \quad (15)$$

where $\mathbf{g}_0' = \mathbf{g}_0 - \boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \mathbf{r}')$. Let us take the Laplace transform of the equation, defined here as $u(\sigma) = \int_0^{+\infty} e^{-i\sigma t} u(t) dt$, where $i^2 = -1$ and where $\sigma = \omega + i\alpha$ is the complex frequency (here in the upper part of the complex plane). We then obtain

TABLE 1 Summary of the boundary conditions for different types of surfaces and discontinuities. The function $F(\omega)$ is given by Lognonné *et al.* (1998) and is associated with the radiating surface

Type of Surface	Stress	Displacement
Solid–solid	$[-p_0 \mathbf{n}_0 \nabla_\Sigma \cdot \mathbf{u} + p_0 \nabla_\Sigma \mathbf{u}(\mathbf{n}_0) + \delta \mathbf{T}_{\text{elastic}} \cdot \mathbf{n}_0]_-^+$	$[\mathbf{u}]_-^+$
Solid–liquid	$[-p_0 \mathbf{n}_0 \nabla_\Sigma \cdot \mathbf{u} + p_0 \nabla_\Sigma \mathbf{u}(\mathbf{n}_0) + \delta \mathbf{T}_{\text{elastic}} \cdot \mathbf{n}_0]_-^+$	$[\mathbf{u} \cdot \mathbf{n}_0 \mathbf{n}_0]_-^+$
Liquid–liquid	$[-p_0 \mathbf{n}_0 \nabla_\Sigma \cdot \mathbf{u} + p_0 \nabla_\Sigma \mathbf{u}(\mathbf{n}_0) + \delta \mathbf{T}_{\text{elastic}} \cdot \mathbf{n}_0]_-^+$	$[\mathbf{u} \cdot \mathbf{n}_0 \mathbf{n}_0]_-^+$
Free solid surface	$\delta \mathbf{T}_{\text{elastic}} \cdot \mathbf{n}_0 = 0$ and $p_0 = 0$	
Free atmospheric surface	$\delta p = \kappa \nabla \cdot \mathbf{u} = 0$	
Radiating atmospheric surface	$\delta p = F(\omega) \rho(\mathbf{g}_0 \cdot \mathbf{n}_0)(\mathbf{u} \cdot \mathbf{n}_0)$	

the expression for the elastodynamic normal modes in the complex frequency domain in operator form:

$$-\sigma^2 \mathbf{u}(\sigma) + \sigma \mathbf{B} \mathbf{u}(\sigma) + \mathbf{A}(\sigma) \mathbf{u}(\sigma) = 0 \quad (16)$$

where the Coriolis operator $\mathbf{B}$ and the elastodynamic-operator $\mathbf{A}$ are expressed by

$$\begin{aligned} \mathbf{B} \mathbf{u}(\sigma) &= 2i\boldsymbol{\Omega} \times \mathbf{u} \\ \mathbf{A}(\sigma) \mathbf{u}(\sigma) &= \frac{1}{\rho_0} [-\nabla \cdot (\mathbf{C} : \nabla \mathbf{u} - \mathbf{u} \cdot \nabla \mathbf{T}_0) + \text{div}(\rho_0 \mathbf{u}) \mathbf{g}'_0 \\ &\quad + \rho_0 \nabla \Phi_1(\mathbf{u})] \end{aligned} \quad (17)$$

Now the only difference between the elastic and non-elastic case is the possible frequency dependence of the stiffness tensor $\mathbf{C}$. Following Valette (1986), the operator $\mathbf{A}$, together with the boundary conditions, can be rewritten in the hydrostatic case and for a free surface as

$$\begin{aligned} \langle \mathbf{v} | \mathbf{A} \mathbf{u} \rangle &= \int dV \mathbf{v} \cdot \mathbf{A} \mathbf{u} = \int dV \left[d^{ijkl} D_k u_l D_i v_j - u^k D_i v_j D_k T_0^{ij} \right. \\ &\quad \left. + \text{div}(\rho_0 \mathbf{u}) \mathbf{g}'_0 \cdot \mathbf{v} + \rho_0 \mathbf{v} \cdot \nabla \Phi_1 \right] \end{aligned} \quad (18)$$

where

$$d^{ijkl} = C^{ijkl} + p_0 g^{ij} g^{kl} - p_0 g^{ik} g^{jl} - p_0 g^{jk} g^{il} \quad (19)$$

with p_0 being the initial pressure and where we have defined the bracket bilinear form

$$\langle \mathbf{v} | \mathbf{u} \rangle = \int_V \rho dV \mathbf{u}(\mathbf{r}) \cdot \mathbf{v}(\mathbf{r}) \quad (20)$$

Other expressions for the operator can be found, such as

$$\begin{aligned} \langle \mathbf{v} | \mathbf{A} \mathbf{u} \rangle &= \int dV [d^{ijkl} D_k u_l D_i v_j + \rho S(\mathbf{u} \cdot \mathbf{g} \text{div}(\mathbf{v}) \\ &\quad - \mathbf{v} \cdot \nabla(\mathbf{u} \cdot \mathbf{g}))] - \int \frac{\nabla \Phi(\mathbf{u}) \cdot \nabla \Phi(\mathbf{v})}{4\pi \mathcal{G}} \\ &\quad - \int_\Sigma S[\mathbf{u} \cdot \mathbf{n}(\mathbf{v}) \cdot \nabla_\Sigma p_0] d\Sigma \end{aligned} \quad (21)$$

where $S(f(\mathbf{u}, \mathbf{v}))$ is the symmetric form $S = \frac{1}{2}(f(\mathbf{u}, \mathbf{v}) + f(\mathbf{v}, \mathbf{u}))$. Expression (21) shows that the gravito-anelastic operator is always symmetric for the bilinear product (20), the latter being a scalar product for real functions only. The Coriolis operator is antisymmetric for this form. For a hermitian scalar product, where the function $\mathbf{v}$ in Eq. (20) is replaced by its complex conjugate, the operator $\mathbf{A}$ is self-adjoint only in the elastic case, while the Coriolis operator is self-adjoint. The elastic, rotating case is therefore a hermitian eigenproblem, while the anelastic case is symmetric. The anelastic, rotating case is more complex and is described in Section 5.

3. Normal Modes of a Spherical NonRotating Elastic Isotropic Earth Model

Normal modes of a spherical nonrotating elastic isotropic (SNREI) Earth constitute for many purposes the basis of normal mode theory, even in an aspherical Earth. They indeed constitute a complete basis of all functions verifying the same boundary and continuity conditions on the spherical surface of the Earth and internal discontinuities, respectively, as shown by Valette (1987) in the elastic case. Normal modes of a spherical Earth can therefore be used to describe the normal modes of all Earth models with any lateral variations but the same spherical shape and discontinuities.

The modern theory for a SNREI model was described by Takeuchi and Saito (1972) and Phinney and Burridge (1973). Let us recall from these works the solution of the SNREI equation

$$\sigma^2 \mathbf{u} = \mathbf{A}_0(\mathbf{u}) \quad (22)$$

where the operator $\mathbf{A}_0$ is defined for a spherically symmetric model such as PREM (Dziewonski and Anderson, 1981). As a consequence of the symmetry, by using group theory arguments, or by a separation of variables, it can be shown that the

eigenfrequencies depend on two integer indices and can be noted $\omega_{l,n}$ and that the normal modes can be expressed in the two following forms:

$$\begin{aligned} \mathbf{u}_{n,l,m}(\mathbf{r}) &= U_{n,l}(r) Y_l^m(\theta, \phi) \mathbf{e}_r + V_{n,l}(r) \nabla Y_l^m(\theta, \phi) \quad \text{or} \\ \mathbf{u}_{n,l,m}(\mathbf{r}) &= W_{n,l}(r) \mathbf{e}_r \times \nabla Y_l^m(\theta, \phi) \end{aligned} \quad (23)$$

Here $\mathbf{e}_r$ is the radial basis vector, n is the radial order, l is a positive integer called the angular order, m is the azimuthal order, such that $-l \leq m \leq l$ and $Y_l^m(\theta, \phi)$ are the spherical harmonic functions. The functions $U_{n,l}$, $V_{n,l}$, or $W_{n,l}$ as well as the real eigenfrequency associated to a given mode depend only on l, n . SNREI normal modes are invariant by a 2π rotation and by a symmetry around the center of the Earth, the latter defining the parity of the mode. Therefore, for the same angular order, we have two types of modes. The first are the spheroidal normal modes, have a null curl and a parity equal to that of l . The second are the toroidal modes, have a null divergence and a parity opposite to that of l .

Theoretically, the basis of SNREI normal modes is made up of all spheroidal and toroidal eigensolutions, including the secular modes with zero eigenfrequency associated with rotation of the fluid parts of the Earth, the gravity modes associated with positive Brunt–Väisälä frequencies in the liquid part and the toroidal core modes. Generally, the seismic modes have a positive index n while the gravity modes have a negative index. However the spectrum is discrete in the seismic band, a continuous spectrum exists in the case of a rotating Earth or if the liquid part of the Earth has a nonzero Brunt–Väisälä frequency (Valette 1989a,b). Only that complete set of eigenfunctions constitutes the complete basis. It is, however, generally accepted that the aspherical seismic normal modes (and seismograms) can be described with the seismic part of this SNREI basis only, i.e., all modes with frequency greater than 0.1 mHz.

The relation (23) involves the gradient of the spherical harmonics functions. To overcome this, Phinney and Burridge (1973) have developed a canonical basis that is more convenient than the spherical basis and more closely related to group theories. In this basis, the vectors are described with complex coordinates and complex basis vectors, and the gradients are incorporated in new functions, called generalized spherical harmonics. We then have

$$\mathbf{u} = u^+ \mathbf{e}_+ + u^0 \mathbf{e}_0 + u^- \mathbf{e}_- \quad (24)$$

where

$$\begin{aligned} \mathbf{e}_- &= \frac{1}{\sqrt{2}}(\mathbf{e}_\theta - i\mathbf{e}_\phi) & \mathbf{e}_0 &= \mathbf{e}_r & \mathbf{e}_+ &= \frac{1}{\sqrt{2}}(-\mathbf{e}_\theta - i\mathbf{e}_\phi) \\ u^- &= \frac{1}{\sqrt{2}}(u_\theta + iu_\phi) & u^0 &= u^r & u^+ &= \frac{1}{\sqrt{2}}(-u_\theta + iu_\phi) \end{aligned} \quad (25)$$

with $\mathbf{e}_\phi$ and $\mathbf{e}_\theta$ being the longitude and co-latitude basis vectors. The eigenfunctions are now expressed with the generalized spherical harmonics of Phinney and Burridge (1973). Both the spherical harmonic or the generalized spherical harmonics are complex functions.

For numerical modeling, a useful further simplification is achieved if the SNREI normal modes are chosen as pure real or imaginary eigenfunctions as well as of a symmetry around the Greenwich plane defining the zero longitude (Lognonné and Romanowicz, 1990a). Such decomposition is generally much more convenient for numerical applications. Table 2 summarizes the different cases of SNREI modes.

The computation of SNREI modes is detailed by Woodhouse (1988) and is briefly summarized here. In the nongravitating case, each spheroidal normal mode is characterized by a vector of four functions, $\mathbf{v} = (\sqrt{2}V, U, \sqrt{2}T_s^{+0}, T_s^{00})$. The first two are the displacements, and the other two are related to the projection of stress on the radial direction. For the

TABLE 2 Summary of the different SNREI modes in the Phinney and Burridge (1973) basis, for the complex and hermitian case and for the real and symmetric ones

Complex Spheroidal Modes	$u^0 = U_{l,n}(r) Y_l^{0m}$	$u^\pm = V_{l,n}(r) Y_l^{\pm m}$
Complex Toroidal Modes	$u^0 = 0$	$u^\pm = \pm i W_{l,n}(r) Y_l^{\pm m}$
Real spheroidal modes		
$m > 0$	$u^0 = U_{l,n}(r) \frac{1}{\sqrt{2}}(Y_l^{0m} + (-1)^m Y_l^{0-m})$	$u^\pm = V_{l,n}(r) \frac{1}{\sqrt{2}}(Y_l^{\pm m} + (-1)^m Y_l^{\pm-m})$
$m = 0$	$u^0 = U_{l,n}(r) Y_l^{00}$	$u^\pm = V_{l,n}(r) Y_l^{\pm 0}$
$m < 0$	$u^0 = U_{l,n}(r) \frac{-i}{\sqrt{2}}(Y_l^{0m} - (-1)^m Y_l^{0-m})$	$u^\pm = V_{l,n}(r) \frac{-i}{\sqrt{2}}(Y_l^{\pm m} - (-1)^m Y_l^{\pm-m})$
Real toroidal modes		
$m > 0$	$u^0 = 0$	$u^\pm = W_{l,n}(r) \frac{\pm i}{\sqrt{2}}(Y_l^{\pm m} + (-1)^m Y_l^{\pm-m})$
$m = 0$	$u^0 = 0$	$u^\pm = \pm i W_{l,n}(r) Y_l^{\pm 0}$
$m < 0$	$u^0 = 0$	$u^\pm = W_{l,n}(r) \frac{\pm 1}{\sqrt{2}}(Y_l^{\pm m} - (-1)^m Y_l^{\pm-m})$

toroidal modes, the set reduces to two functions, $\mathbf{v} = (\sqrt{2}W, \sqrt{2}T_r^{+0})$, being the horizontal displacement and the radial projection of stress, respectively. In the gravitating case, the set is expanded into functions for the spheroidal modes only, in order to account for the mass redistribution. In both cases, the normal mode equation (3) and the constitutive equation (8) yield a propagator equation defining the normal modes:

$$\frac{d\mathbf{v}}{dr} = \mathbf{M}\mathbf{v} \quad (26)$$

where $\mathbf{v}$ is continuous across boundaries. The propagator matrix $\mathbf{M}$ is given by Phinney and Burridge (1973) for both the spheroidal and toroidal cases. The resolution of normal modes is generally performed by starting from the center of the Earth (or from a shallower depth for modes confined more closely to the surface) for two initial conditions corresponding to $\mathbf{v} = (0, 0, 1, 0)$ and $\mathbf{v} = (0, 0, 0, 1)$, respectively. The propagation of these functions toward the surface produces two vectors $\mathbf{v}_1$ and $\mathbf{v}_2$, both depending on the frequency. Eigenmodes and eigenfrequencies are then obtained by finding the frequency ω and real number β such that

$$v_{1,3}(a, \omega) + \beta v_{2,3}(a, \omega) = 0, \quad v_{1,4}(a, \omega) + \beta v_{2,4}(a, \omega) = 0 \quad (27)$$

where $v_{1,i}$ and $v_{2,i}$ are the i th components of vectors $\mathbf{v}_1$ and $\mathbf{v}_2$, respectively. The MINEOS software (G. Masters, personal communication, 1999), necessary for the computation of normal modes for a SNREI model can be found on the attached Handbook CD, and was developed by Gilbert, Masters, and Woodhouse. See Woodhouse (1988) for more details. It allows the computation of modes for a SNREI model with a free surface at the top of the model (either solid or fluid). An estimate of the quality factor Q is also computed following first-order perturbation theory.

Figure 1 shows the different eigenfrequencies found for an Earth model with a solid part described by the PREM model and an atmospheric part described by the US Standard atmospheric model (US Standard Atmosphere, 1976). Four different types of normal modes are found: The first ones are related to the spheroidal modes of the solid Earth, with the fundamental branch ${}_0S_l$. The second are related to the Tsunami modes, which have almost all their energy localized in the oceanic layer of PREM. Note that the group velocity of these modes depends weakly on the frequency, in contrast to the fundamental spheroidal branch. The third and fourth are related to the acoustic and gravity modes of the atmosphere, the latter generally described with negative radial index. With the exception of the fundamental branch of acoustic modes, these modes have their eigenfrequency varying with the height of the top of the model atmosphere, as well as with the type of boundary condition—free, rigid, or radiative (Watada, 1995).

FIGURE 1 The different eigenfrequencies found for an Earth model with a solid part described by the PREM model and an atmospheric part described by the US Standard Atmospheric Model (1976) in logarithmic scale. Note that the group velocity of tsunamis, and the group velocity of the Lamb modes are constant. The intersection between the fundamental acoustic mode and the Lamb mode is an artifact of the boundary condition, here a free surface at the top of atmosphere artificially limited to 150 km of altitude. The spacing between the acoustic modes depends also on the height of the atmospheric model.

The solid Earth mode frequencies, either spheroidal (Fig. 2a), or toroidal (Fig. 2b) have frequencies and amplitudes that are practically unaffected by the energy transferred in the atmosphere. Their properties in terms of propagation in the solid Earth are therefore adequately described by an Earth with a free surface at the base of the atmosphere. Figure 3 shows the vertical amplitude with depth of the normal modes ${}_nS_{20}$, for increasing radial order n .

4. Normal Modes of a Spherical Nonrotating Anelastic Isotropic Earth Model

Attenuation or a radiating surface affect the normal modes due to the nonconservation of energy. For intrinsic attenuation and at a given frequency, this implies an imaginary part of the stiffness tensor, as shown by Liu *et al.* (1976) and Anderson and Given (1982). For causality reasons originally demonstrated for similar problems by Kramers and Kronig, this also implies a frequency dependence of the stiffness tensor (Anderson, 1989; Anderson and Minster, 1979), which in seismology is necessary to reconcile normal mode and body

FIGURE 2 The solid Earth eigenfrequencies for (a) spheroidal modes and (b) toroidal modes in linear scale. Note for the spheroidal mode the bifurcation between the surface wave type modes and the two Stoneley modes branch, both with a constant group velocities, and respectively associated to modes trapped at the CMB and ICB boundary. The dispersion branches above the ICB Stoneley mode branch show also several bifurcations, related to the superposition of three types of mode family, respectively associated to ScS , PKIKP, and core-associated modes (Dahlen and Tromp, 1998).

FIGURE 3 Vertical amplitude (heavy line) and imaginary amplitude (light line) for modes of angular order $l=20$ and increasing radial order n . Both amplitudes are multiplied by the square root of the density, and are therefore proportional to the square root of the kinetic energy distribution. Amplitude for the imaginary part is multiplied by 10.

wave mean velocity models (Kanamori and Anderson, 1977; Montagner and Kennett, 1996).

The computation of the normal modes of a SNRAI Earth can be performed using the complete basis of the SNREI normal modes (Lognonné, 1989; Tromp and Dahlen, 1990; Clévéde, 1991). The solution, for each n and l value, is then expressed as a summation of these functions:

$$\mathbf{v} = \sum_{n'} c_{n' l} \mathbf{u}_l \quad (28)$$

where the indexes n, l are omitted in $\mathbf{v}$ and $c_{n'}$ for simplicity. The spherical anelastic perturbation implies coupling between modes with different values of n , but the same value of l and m . This formulation can then be used to find the normal modes, e.g., the coefficients $c'_{n'}$ and the eigenfrequencies. Starting from

$$\omega^2 \mathbf{v} = \mathbf{A}(\omega) \mathbf{v} \quad (29)$$

by a second-order Taylor expansion around the frequency ω_0 we first get

$$\omega^2 \mathbf{v} = [\mathbf{A}(\omega_0) + (\omega - \omega_0) \partial_\omega \mathbf{A}(\omega_0) + \frac{1}{2}(\omega - \omega_0)^2 \partial_\omega^2 \mathbf{A}(\omega_0)] \mathbf{v} \quad (30)$$

and we can then express the second-order problem as a first-order matrix problem. See Park and Gilbert (1986) for another example of this technique. We finally get

$$\begin{aligned} & \omega \left(1 - \frac{1}{2} \partial_\omega^2 A \right) \begin{pmatrix} \omega \mathbf{v} \\ \mathbf{v} \end{pmatrix} \\ &= \begin{pmatrix} \partial_\omega A - \omega_0 \partial_\omega^2 A & A(\omega_0) - \omega_0 \partial_\omega A + \frac{\omega_0^2}{2} \partial_\omega^2 A \\ 1 - \frac{1}{2} \partial_\omega^2 A & 0 \end{pmatrix} \begin{pmatrix} \omega \mathbf{v} \\ \mathbf{v} \end{pmatrix} \end{aligned} \quad (31)$$

Classical EISPACK routines (Smith *et al.*, 1976) can be used to solve this problem. This improved theory affects the value of the attenuation factor Q of the modes slightly, by 2–3%, as well as the amplitudes of modes by comparable relative effects. It also produces an initial delay of the modes, typically of 0.5–2 sec, which may have to be taken into account for very precise source analysis.

The effect of the atmosphere is comparable and also leads to the escape of seismic energy. It is described in detail by Lognonné *et al.* (1998), and is related to a boundary term having a frequency dependence (Table 1). Although not affecting frequency, attenuation, or modal amplitudes in the solid Earth in an observable way, it must obviously be taken

into account when modes are excited by atmospheric sources or when seismic signals are observed in the atmosphere (Artru *et al.*, 2001). This is the case for explosions and atmospheric stochastic turbulences. Figure 4 shows both the effects of the atmosphere and of the PREM attenuation model, when the dispersion law of Liu *et al.* (1976) is taken into account in the computation of normal mode fundamental branches. The atmospheric displacement of normal modes is at the origin of the atypical excitation of normal modes by strong atmospheric explosion, such as the Pinatubo explosion (Kanamori and Mori, 1992; Kanamori *et al.*, 1994; Zurn and Widmer, 1996).

5. Normal Modes and Seismograms in the General Aspherical Case

5.1 Normal Mode Orthonormality Relations

In the general case, normal modes cannot be described by a single spherical harmonic and have a more complicated shape on the sphere. Many general properties remain, however. In the general case, following Lognonné (1991), let us first consider the right eigenmodes $|\mathbf{u}_k\rangle$ and associated eigenfrequencies σ_k satisfying

$$-\sigma_k^2 |\mathbf{u}_k\rangle + \sigma_k \mathbf{B} |\mathbf{u}_k\rangle + \mathbf{A}(\sigma_k) |\mathbf{u}_k\rangle = 0 \quad (32)$$

and the left eigenmodes, with left eigenfunctions $\langle \mathbf{v}_k |$ and their associated eigenfrequencies σ_k verifying

$$-\sigma_k^2 \langle \mathbf{v}_k | + \sigma_k \langle \mathbf{v}_k | \mathbf{B}^\dagger + \langle \mathbf{v}_k | \mathbf{A}^\dagger(\sigma_k) = 0 \quad (33)$$

Here † denotes the left dual operator, defined here as $\langle \mathbf{v} | \mathbf{A} \mathbf{u} \rangle = \langle \mathbf{A}^\dagger \mathbf{v} | \mathbf{u} \rangle$. As shown by Lognonné (1991), and due to the antisymmetry of operator $\mathbf{B}$ and symmetry of operator $\mathbf{A}$, the left or dual normal modes are solutions of the right eigenproblem with the inverted rotation

$$-\sigma_k^2 |\mathbf{v}_k\rangle - \sigma_k \mathbf{B} |\mathbf{v}_k\rangle + \mathbf{A}(\sigma_k) |\mathbf{v}_k\rangle = 0 \quad (34)$$

and have the same eigenvalues as the primal normal modes, despite different eigenfunctions. The relation between the primal and dual mode is trivial only in a few cases (Table 3), such as the elastic case, where the dual eigenmode is simply the complex conjugate of the primal mode, or in the axisymmetric rotating and anelastic case, where $|\mathbf{v}_k\rangle = |\mathbf{S} \mathbf{u}_k\rangle$, $\mathbf{S}$ being an orthogonal symmetry around a plane containing the rotation axis. In the general case, eigenfrequencies exist also with either a positive or negative real part of the frequency. However, the gravito-elastic operator is such that $\mathbf{A}^*(\sigma) = \mathbf{A}(-\sigma^*)$, so that the complex conjugate of (32) shows that each eigenfrequency σ_k and associated eigenmode $|\mathbf{u}_k\rangle$

FIGURE 4 The vertical amplitude of the fundamental spheroidal mode with respect to radius and angular order l in the upper mantle and atmosphere, for a radiative boundary condition at an altitude of 150 km. (a) Real part multiplied by 100 in the atmosphere; (b) imaginary part multiplied by 10 in the solid Earth. The amplitude in both examples is multiplied by the square root of density, and is therefore proportional to the square root of the kinetic energy distribution. Note the transition between trapped atmospheric extensions and untrapped ones. In the solid Earth, note the shallow increasing amplitudes with the increasing angular order as well as the increasing amplitude in the low-velocity–high-attenuation zone of the upper mantle.

TABLE 3 Summary of the different cases for the dual mode and orthogonality relations depending on the inclusion of attenuation and rotation in the theory

Case	Normal Mode Equation	Dual Mode	Orthogonality
Nonrotating elastic	$[-\sigma^2 + \mathbf{A}_0] \mathbf{u}\rangle = 0$		$\langle \mathbf{v}_{k'} \mathbf{u}_k \rangle = \delta_{kk'}$
Complex case		$ \mathbf{u}^*\rangle$	
Real case		$ \mathbf{u}\rangle$	
Rotating elastic	$[-\sigma^2 + \sigma \mathbf{B} + \mathbf{A}_0] \mathbf{u}\rangle = 0$	$ \mathbf{u}^*\rangle$	$\langle \mathbf{v}_{k'} \mathbf{u}_k \rangle - \frac{1}{\sigma_k + \sigma_{k'}} \langle \mathbf{v}_{k'} \mathbf{B} \mathbf{u}_k \rangle = \delta_{kk'}$
Nonrotating anelastic	$[-\sigma^2 + \mathbf{A}_0(\sigma)] \mathbf{u}\rangle = 0$	$ \mathbf{u}\rangle$	$\langle \mathbf{v}_{k'} \mathbf{u}_k \rangle - \frac{\langle \mathbf{v}_{k'} \mathbf{A}(\sigma_{k'}) \mathbf{u}_k \rangle - \langle \mathbf{v}_{k'} \mathbf{A}(\sigma_k) \mathbf{u}_k \rangle}{\sigma_{k'}^2 - \sigma_k^2} = \delta_{kk'}$
Axisymmetric rotating anelastic	$[-\sigma^2 + \sigma \mathbf{B} + \mathbf{A}(\sigma)] \mathbf{u}\rangle = 0$	$ \mathbf{S} \mathbf{u}\rangle$	Eqs. (35)–(36)
Aspherical rotating anelastic	$[-\sigma^2 + \sigma \mathbf{B} + \mathbf{A}(\sigma)] \mathbf{u}\rangle = 0$	Solution of Eq. (34)	Eqs. (35)–(36)

imply that the pair $-\sigma_k^*$ and $|\mathbf{u}_k^*\rangle$ are also eigenfrequency, and eigenmode, respectively.

Let us consider two singlets k and k' with different eigenfrequencies, multiply the relations (32) and (33) by $\langle \mathbf{v}_{k'} |$ and $|\mathbf{u}_k\rangle$ respectively, make the difference of the two obtained relations and divide the result by $\sigma_{k'}^2 - \sigma_k^2$. We finally get the following bi-orthogonality relation, with bracket product

related to the aspherical density:

$$\langle \mathbf{v}_{k'} | \mathbf{u}_k \rangle - \frac{1}{\sigma_k + \sigma_{k'}} \times \left[\langle \mathbf{v}_{k'} | \mathbf{B} \mathbf{u}_k \rangle + \frac{\langle \mathbf{v}_{k'} | \mathbf{A}(\sigma_{k'}) \mathbf{u}_k \rangle - \langle \mathbf{v}_{k'} | \mathbf{A}(\sigma_k) \mathbf{u}_k \rangle}{\sigma_{k'} - \sigma_k} \right] = 0 \quad (35)$$

The relation (35) defines the general bi-orthogonality relation between the modes associated with two different eigenfrequencies. The limit for two identical modes defines the normalization, so that

$$\begin{aligned} \langle \mathbf{v}_k | \mathbf{u}_k \rangle - \frac{1}{2\sigma_k} [\langle \mathbf{v}_k | \mathbf{B} \mathbf{u}_k \rangle + \langle \mathbf{v}_k | \partial_\sigma \mathbf{A}(\sigma_k) \mathbf{u}_k \rangle] \\ = -\frac{1}{2\sigma_k} \langle \mathbf{v}_k | \partial_\sigma \mathbf{H}(\sigma_k) \mathbf{u}_k \rangle = 1 \end{aligned} \quad (36)$$

where $\mathbf{H} = -\sigma^2 + \sigma \mathbf{B} + \mathbf{A}(\sigma)$. The elastic limit gives the orthogonality relation obtained by Dahlen and Smith (1975) for a rotating elastic case:

$$\langle \mathbf{v}_{k'}^* | \mathbf{u}_k \rangle - \frac{1}{\omega_k + \omega_{k'}} \langle \mathbf{v}_{k'}^* | \mathbf{B} \mathbf{u}_k \rangle = \delta_{kk'} \quad (37)$$

6. Mode Summation and Seismograms

In the general case, as well as in the different simplified cases (e.g., Gilbert, 1970, in the elastic case), normal modes can be used for computing the response of the Earth produced by an equivalent body force $|\mathbf{f}(t)\rangle$. In the frequency domain, the solution has to satisfy

$$[-\sigma^2 + \sigma \mathbf{B} + \mathbf{A}] \mathbf{u}(\sigma) = |\mathbf{f}(\sigma)\rangle \quad (38)$$

and can moreover be expressed as a projection in the complete basis of eigenfunctions such as

$$|\mathbf{u}(\sigma)\rangle = \sum_{k'} c_{k'}(\sigma) |\mathbf{u}_{k'}\rangle \quad (39)$$

As noted above, we will restrict the summation to the seismic modes (e.g., with a period less than 1 h), but for both the positive and negative frequencies. The time expression of the seismogram, given by

$$|\mathbf{u}(t)\rangle = \frac{1}{2\pi} \int_{i\epsilon-\infty}^{i\epsilon+\infty} |\mathbf{u}(\sigma)\rangle e^{i\sigma t} d\sigma \quad (40)$$

can then be obtained by closing the integration path, using relation (35) and the Cauchy theorem. Following Lognonné (1991) we then get

$$|\mathbf{u}(t)\rangle = H(t) \sum_k e^{i\sigma_k t} \lim_{\sigma \rightarrow \sigma_k} i(\sigma - \sigma_k) c_k(\sigma) |\mathbf{u}_k\rangle \quad (41)$$

For an impulsive source, the limit is found to be

$$\lim_{\sigma \rightarrow \sigma_k} i(\sigma - \sigma_k) c_k(\sigma) = \frac{i \langle \mathbf{v}_k | \mathbf{f} \rangle}{\langle \mathbf{v}_k | \partial_\sigma \mathbf{H}(\sigma_k) \mathbf{u}_k \rangle} = \frac{\langle \mathbf{v}_k | \mathbf{f} \rangle}{2i\sigma_k} \quad (42)$$

The response of the Earth to an impulsive equivalent body force is obtained from the summation over all positive and negative indices, i.e., positive frequencies as well as negative frequencies. This finally allows recovery of a real amplitude for the Green tensor, equal to

$$|\mathbf{u}(t)\rangle = H(t) \sum_{k>0} \Re \left(\frac{1}{i\sigma_k} \langle \mathbf{v}_k | \mathbf{f} \rangle e^{i\sigma_k t} |\mathbf{u}_k\rangle \right) \quad (43)$$

where $\Re$ denotes the real part. Table 4 describes several cases that can be derived from this Green's function by a convolution. Note also that Eqs. (38) and (39) can also be used to compute the amplitude produced by nonlocal sources, such as tidal forces or atmospheric forces, by a double convolution in space and time.

The last step corresponds to instrumental transfer function between the ground displacement, as expressed by relations in Table 4, and the digital data. This transfer function is defined as the receiver function. It therefore clearly depends on the type of instruments. For seismometers, the signal is the sum of all inertial forces (ground acceleration and gravity forces), projected along the measurement direction and, when appropriate, filtered by the frequency transfer function of the instrument. The measurement direction $\nu(t)$ as well as the position of the instrument varies with time due to the tilt, so that $\nu(t) = \nu_0 - \nabla_\Sigma \mathbf{u}(\nu_0)$. Without the filtering term, we therefore have to first order:

$$\begin{aligned} \langle \mathbf{R} | \mathbf{u} \rangle &= \nu(t) \cdot (\mathbf{g}(t, \mathbf{r}') - [\partial_t^2 \mathbf{u} + 2\boldsymbol{\Omega} \times \partial_t \mathbf{u}]) - \nu_0 \cdot \mathbf{g}_0(\mathbf{r}) \\ &= -\nu_0 \cdot [\partial_t^2 \mathbf{u} + 2\boldsymbol{\Omega} \times \partial_t \mathbf{u}] - \nu_0 \cdot \nabla \Phi_1 + \nu_0 \cdot (\mathbf{u} \cdot \nabla \mathbf{g}_0) \\ &\quad - \mathbf{g}_0 \cdot \nabla_\Sigma \mathbf{u}(\nu_0) \end{aligned} \quad (44)$$

TABLE 4 Amplitude of the ground displacement as described by a summation of normal modes for a local double couple. The index s denotes the position of the source

Source Function	Displacement Expression
Seismic tensor with general source function $ \mathbf{f}(t)\rangle = -\mathbf{M}(t) \nabla \delta(\mathbf{r} - \mathbf{r}_s)$	$ \mathbf{u}(t)\rangle = \sum_{k>0} \Re \left(\frac{1}{i\sigma_k} \int_0^t dt' \mathbf{M}(t') : \nabla \mathbf{v}_k(\mathbf{r}_s) e^{i\sigma_k(t-t')} \mathbf{u}_k\rangle \right)$
Seismic tensor with Heaviside source function $ \mathbf{f}(t)\rangle = -\mathbf{M}_0 H(t) \nabla \delta(\mathbf{r} - \mathbf{r}_s)$	$ \mathbf{u}(t)\rangle = H(t) \sum_{k>0} \Re \left(\frac{1}{\sigma_k^2} \mathbf{M}_0 : \nabla \mathbf{v}_k(\mathbf{r}_s) (1 - e^{i\sigma_k t}) \mathbf{u}_k\rangle \right)$

where $\mathbf{g}_0$ includes both the gravitational and centrifugal terms. The contributions of the nonground acceleration terms are significant for normal modes with angular orders less than 10 generally, and are therefore related to the Coriolis acceleration, the perturbation of gravity, free air correction, and surface tilt, respectively. The last term related to free air correction is in phase with the acceleration, while the term related to the mass redistribution is generally in opposition phase. Table 5 gives the projected terms along the horizontal and vertical components.

The source function in Table 4 can be expressed in the same way. For a seismic tensor moment, we have

$$\begin{aligned} \langle \mathbf{v}_k | \mathbf{S} \rangle &= -\epsilon_{\alpha\beta} M^{\alpha\beta} \\ &= \epsilon_{00} M^{00} + 2\epsilon_{+-} M^{+-} + 4\Re(\epsilon_{+0} M^{+0}) + 4\Re(\epsilon_{++} M^{++}) \end{aligned} \quad (45)$$

where $M^{\alpha\beta}$ are the canonical covariant components of the seismic moment tensor in the Phinney and Burridge (1973) basis, and where $\epsilon_{\alpha\beta}$ are the contravariant components of the dual stress tensor, defined as $e_{\alpha\alpha'} e_{\beta\beta'} \epsilon^{\alpha'\beta'}$. We used the symmetry relations $M^{\alpha\beta} = (-1)^{\alpha+\beta} M^{-\alpha-\beta*}$. For an elastic Earth, $|\mathbf{v}\rangle = |\mathbf{u}^*\rangle$, and then $\epsilon_{\alpha\beta} = (\epsilon^{\alpha\beta})^*$. Table 6 gives the expressions of the seismic tensor for a centroid moment tensor source.

For atmospheric sources, a seismic moment can also be used for the representation of the source density in the fluid parts of the Earth, ocean, or atmosphere, by using the generalization of Lognonné *et al.* (1994). In the latter case, we can decompose the excess pressure $\Delta p = p_{\text{true}} - p_{\text{Hooke}}$ into nonlaminar and laminar contributions: $\Delta p = \delta p - \frac{1}{2} \rho v^2$, and then get

$$M^{\alpha\beta} = -\delta p e^{\alpha\beta} + \rho \left(\frac{1}{2} |v|^2 e^{\alpha\beta} - v^\alpha v^\beta \right) \quad (46)$$

where v^α is the α component of the velocity of the fluid in the atmosphere and $|v|$ is the amplitude of the velocity. This

TABLE 5 Expression of the receiver functions: u_r, u_θ, u_ϕ are the components of $\mathbf{u}$ in a spherical basis, and θ is the colatitude. Ω_0 is the rotation vector of the Earth. $\phi_r, \phi_\theta, \phi_\phi$ are the components of $\nabla\phi$

Z-axis seismometer	$\langle \mathbf{R}_Z \mathbf{u}_k \rangle$	$\sigma_k^2 u_r - 2i\Omega_0 \sigma_k u_\theta \sin \theta - \phi_r + \frac{2u_r g_0}{r}$
S-axis seismometer	$\langle \mathbf{R}_S \mathbf{u}_k \rangle$	$\sigma_k^2 u_\theta - 2i\Omega_0 \sigma_k (-\sin \theta u_r - \cos \theta u_\phi) - \phi_\theta + g_0 D_\theta u_r$
W-axis seismometer	$\langle \mathbf{R}_W \mathbf{u}_k \rangle$	$\sigma_k^2 u_\phi - 2i\Omega_0 \sigma_k \cos \theta u_\theta - \phi_\phi + g_0 D_\phi u_r$

TABLE 6 Relation between the canonical component of the seismic tensor and those in the spherical basis

M^{00}	M_{rr}
M^{+-}	$-\frac{1}{2}(M_{\theta\theta} + M_{\phi\phi})$

M^{++}	$1/2(M_{\theta\theta} - M_{\phi\phi}) - iM_{\theta\phi}$

generalizes the incomplete source proposed by Tanimoto (1999) for the explanation of the permanent excitation of the atmosphere.

7. Normal Modes of a Rotating, Aspherical, Anelastic, and Anisotropic (RA₃) Earth Model: Perturbation Theory

As noted in the introduction, the early observations almost immediately pointed out the limits of the spherical Earth theory and showed that the departure of sphericity and rotation resulted in an observable degeneracy of the singlets. For each normal mode multiplet, the frequencies of the $2l+1$ singlets are therefore slightly different, and each has excitation and observation amplitude depending on the position of both the source and station and on the mechanism of the earthquake. Therefore, the superposition of all singlet peaks is done differently for all receiver–source pairs. As a consequence, the shape and maximum of the spectral peaks associated with a given normal mode varies with the source–receiver pair, which provides a unique source of information for the determination of lateral variations of the Earth (Fig. 5). Let us now therefore describe the forward problem necessary for the computation of seismograms, spectra or secondary data for a general RA₃ Earth model.

This 3D model can be seen as the superposition of a mean model and a 3D de-meaned structure. For all realistic Earth models, the integrated power spectrum of the 3D lateral variations is small compared to the 1D structure, even if large 3D variations may exist locally. In that respect, 3D lateral variations act as small perturbations superimposed on the reference spherical elastic Earth, the latter being associated with a given elastodynamic operator $\mathbf{A}_0$. This reference model is not necessarily the mean Earth model of the RA₃, and the perturbation has therefore generally a mean component, as for example for the couple PREM (Dziewonski and Anderson, 1981) and M84A/C of Woodhouse and Dziewonski (1984). Note that the eigenfunctions of the reference operator are defined generally for the spherical volume corresponding to the spherical Earth, e.g., for a sphere with 6371 km radius in the case of PREM. Because the perturbations related to lateral variations and asphericity are relatively small, perturbation theory is therefore well suited to model these effects. Note that such perturbation theory is also extensively used in quantum mechanics (e.g., Cohen-Tannoudji *et al.*, 1980).

7.1 The Perturbation of Asphericity, Rotation, and Lateral Heterogeneities

The first and theoretically most constraining perturbation is related to the asphericity of the boundary conditions, especially

FIGURE 5 Selection of normal modes peaks for ${}_0S_9$, ${}_1S_4$, ${}_4S_4$, and ${}_0T_9$. The power spectra are obtained by a FFT performed on seismograms corrected from the drift and tides, and then tapered by an Hanning window. The selection was performed from a series of records of the IDA (Agnew *et al.*, 1976), GEOSCOPE (Romanowicz *et al.*, 1991), and IRIS networks, for earthquakes with M_s magnitudes greater than 7 (Nawab, 1993). Bars on the frequency axis indicate the frequencies of the singlets for a rotating elliptical spherical earth.

the free surface and all liquid–solid boundary conditions. Indeed, all perturbation theories or variational theories use as complete basis the eigenfunctions of the reference operator. With the latter, the eigenfunctions of the perturbed operator are computed, but only for the same volume as the spherical Earth and for the same set of discontinuities.

The first step is therefore to map the aspherical shape of the 3D Earth model into a spherical shape. Today, this is well described only for an ellipsoidal Earth. For such an ellipsoidal Earth, with a shape obtained with modern refinement of the Clairaut equation (Clairaut, 1743; Jeffreys, 1971; Bullen, 1973), each iso-density surface ($\rho(r') = \text{constant value}$) in the real aspherical volume (where r' is the radius) is mapped to an iso-radius surface ($r = \text{constant value}$) in the mapped spherical volume. To first order, the mapped elastodynamic operator can be written as (Woodhouse and Dahlen, 1978; Woodhouse, 1980):

$$\mathbf{A}(r', \theta', \phi') = \mathbf{A}_0(r, \theta, \phi) + \delta\mathbf{A}_e(r, \theta, \phi) \quad (47)$$

where $\mathbf{A}_0$ is the spherical operator, and where the perturbation $\delta\mathbf{A}_e$, given by Woodhouse (1980), expresses the effect of shape and discontinuities asphericities. Note here that on the left side, r' is the real radius, and θ' and ϕ' are the geographical coordinates. On the right side, however, θ and ϕ are the geocentric coordinates, and r is the mapped radius. For an elliptical Earth, the geocentric and geographic longitudes are equal, while $0 < r < a$ and $\theta = \arctan\{[1 + 2\epsilon(r)]\tan\theta'\}$, where ϵ is the

flattening coefficient. In all the following expressions, including the computation of seismograms, only geocentric coordinates and mapped radius will be used. The lateral variations in the shape of the free surface or internal discontinuities produce a perturbation, for which the first-order expression is given by Woodhouse (1980) and which will be noted hereafter $\delta\mathbf{A}_h(r, \theta, \phi)$. The generalization to higher orders of the geographic/geocentric mapping for such an aspherical Earth is nontrivial and has not yet been achieved.

With this mapping, the SNREI or SNRAI normal modes can be used as a complete basis of functions defined in the unperturbed volume $\mathcal{V}_0$. Any function verifying the boundary conditions in $\mathcal{V}_0$ can then be written as

$$|\mathbf{u}\rangle = \sum_{l,m,n} c_{l,m,n} |l, m, n\rangle \quad (48)$$

where $|l, m, n\rangle$ are the spherical eigenfunctions. This decomposition will be the basis of perturbation theories or variational methods for the resolution of the aspherical problem.

The last part of the perturbation is related to volumetric perturbations, such as lateral variations of elastic or anelastic structure. Finally, the operator can be written as

$$\begin{aligned} \mathbf{A}(r', \theta', \phi') &= \mathbf{A}_0(r, \theta, \phi) + \delta\mathbf{A}_e(r, \theta, \phi) + \delta\mathbf{A}_s(r, \theta, \phi) \\ &\quad + \delta\mathbf{A}_h(r, \theta, \phi) \\ &= \mathbf{A}_0(r, \theta, \phi) + \delta\mathbf{A}(r, \theta, \phi) \end{aligned} \quad (49)$$

where $\delta\mathbf{A}_h$ and $\delta\mathbf{A}_s$ are the perturbations of boundaries and volumetric lateral heterogeneities, respectively. Note here that the lateral heterogeneities are those after mapping, i.e., at their geocentric coordinates. The summation of the three terms is the perturbation of the operator $\mathbf{A}$. It is linear with respect to the structure and linearized for the interface and ellipticity perturbations.

The last perturbation is now related to the introduction of rotation, which was neglected in the SNRAI model. We end up with the expression of the eigenproblem of an aspherical, laterally heterogeneous, and anelastic Earth, which can be written in Hamiltonian form as

$$\sigma^2|\mathbf{u}\rangle = [\mathbf{H}_0 + \delta\mathbf{H}(\sigma)]|\mathbf{u}\rangle \quad (50)$$

Around a frequency σ_0 , this can be rewritten with the following operators:

$$\begin{aligned} \mathbf{H}_0 &= \mathbf{A}_0(\sigma_0), \\ \delta\mathbf{H}(\sigma) &= -\sigma^2\delta\mathbf{K} + \sigma\mathbf{B} + \mathbf{A}_0(\sigma) - \mathbf{A}_0(\sigma_0) + \delta\mathbf{A}(\sigma) \end{aligned} \quad (51)$$

where we recognize in the perturbations the terms related to the density perturbation $\delta\mathbf{K} = \delta\rho$, to the Coriolis operator with perturbed density $\mathbf{B}$, to the physical dispersion of the spherical operator, and lastly to the perturbation in structure, shape, and boundary $\delta\mathbf{A}$.

8. Higher-Order Perturbation Theory

Let us now consider a singlet k and note its eigenfrequency σ_k . The associated primal eigenfunction $|\mathbf{u}_k\rangle$ and dual eigenfunction $|\mathbf{v}_k\rangle$ verify

$$\begin{aligned} \lambda_k|\mathbf{u}_k\rangle &= \mathbf{H}(\lambda_k)|\mathbf{u}_k\rangle \\ \lambda_k|\mathbf{v}_k\rangle &= \hat{\mathbf{H}}(\lambda_k)|\mathbf{v}_k\rangle \end{aligned} \quad (52)$$

where $\lambda_k = \sigma_k^2$ is the squared frequency and $\hat{\mathbf{H}}$ is the dual operator with reversed rotation. They have to follow the bi-orthogonality relation (35) and to be normalized with (36). All the singlets of the multiplet K characterized by l and n in the reference model will define a subspace of the spectrum noted $\mathcal{S}_K$ and with a $2l + 1$ dimension. In the nonrotating, anelastic case, $\mathbf{H}$ is a self-dual operator and the dual and primal eigenmodes are identical for the real scalar product. Let us now concentrate on the primal eigenfunction (all dual expressions might be obtained by substituting $\mathbf{H}$ by $\hat{\mathbf{H}}$ and the primal modes by their duals, the eigenfrequencies of the dual and primal modes, as well as all perturbations of eigenfrequencies being identical). Assuming that all eigenmodes and eigenfrequencies can be expanded in terms of a power series of a small parameter ϵ , related to the

perturbation $\delta\mathbf{H}$, we can thus write

$$\lambda_k = \sigma_k^2 = \lambda_K + \delta_1\lambda_k + \delta_2\lambda_k + \dots \quad (53)$$

$$|\mathbf{u}_k\rangle = |\mathbf{u}_k^{(0)}\rangle + |\mathbf{u}_k^{(1)}\rangle + |\mathbf{u}_k^{(2)}\rangle + \dots \quad (54)$$

where $\lambda_k = \sigma_k^2$ is the squared frequency of the spherical normal mode in the reference operator, $\delta_n\lambda_k$ and $|\mathbf{u}_k^{(n)}\rangle$ are the n th-order perturbations in the squared eigenfrequency and eigenmode of the singlet k , respectively. All the eigenmode perturbations will be described in the SNRAI/SNREI basis by

$$|\mathbf{u}_k^{(p)}\rangle = \sum_j c_{n,l,m}^p |n, l, m\rangle \quad (55)$$

Following Lognonné (1991), we leave the perturbation path open, by decomposing it into several incremental perturbations, and introduce a renormalization operator. This gives

$$\begin{aligned} \delta\mathbf{H}(\lambda) &= \delta\mathbf{H}(\lambda_K) + (\lambda - \lambda_K) \frac{\partial\delta\mathbf{H}}{\partial\lambda}(\lambda_K) + \dots \\ &= \delta_1\mathbf{H} + \delta_2\mathbf{H} + \dots \end{aligned} \quad (56)$$

where

$$\begin{aligned} \delta\mathbf{H}(\lambda_K) &= -\sigma_K^2\delta\mathbf{K} + \sigma_K\mathbf{B} + \delta\mathbf{A}(\sigma_K), \\ \frac{\partial\delta\mathbf{H}}{\partial\lambda}(\lambda_K) &= -2\sigma_K\delta\mathbf{K} + [\mathbf{B} + \partial_\sigma\mathbf{A}(\sigma_K)] \end{aligned}$$

and where $\delta_1\mathbf{H}$, $\delta_2\mathbf{H}$ are the succession of perturbation paths of increasing orders. Note the Coriolis operator in the coupling terms, which is producing strong coupling between toroidal and spheroidal modes at long period, as shown by Masters *et al.* (1983).

For the sake of simplicity, we assume here that the perturbation of the bi-orthonormality relation is weaker than the Hamiltonian, and can be written as

$$1 = \mathbf{N}_0 + \delta_2\mathbf{N} + \delta_3\mathbf{N} + \dots \quad (57)$$

where the renormalization operator $\mathbf{N}_0$ incorporates potential first-order perturbations in the subspace $\mathcal{S}_K$, but with all coupling perturbations in $\delta_2\mathbf{N}$. The general case is shown by Lognonné (1991), and here we can assume that the second-order perturbation operators $\delta_2\mathbf{H}$ and third-order one $\delta_3\mathbf{N}$ and higher orders can be assumed nonzero only in the subspace $\mathcal{S}_K$. Note that a slightly different method, valid to the second order, was developed using subspace projection (e.g., Dahlen 1987; Park, 1990b).

The only constraint imposed by Eqs. (56)–(57) at this stage is to have a sum equal to the real perturbation. We will see later that this freedom is crucial for the efficiency of the perturbation procedure. Let us indeed solve the equation of normal modes by developing the perturbation terms by increasing order and focus on the first- and second-order

perturbations. Starting from

$$\lambda_k |\mathbf{u}_k\rangle = [\mathbf{H}_0 + \delta \mathbf{H}] |\mathbf{u}_k\rangle \quad (58)$$

we get, after development, the following expression

$$\begin{aligned} 0 &= [\lambda_k - \mathbf{H}_0 - \delta \mathbf{H}] |\mathbf{u}_k\rangle \\ &= [\lambda_K - \mathbf{H}_0] |\mathbf{u}_k^{(0)}\rangle \\ &\quad + [\delta_1 \lambda_k \mathbf{N}_0 - \delta_1 \mathbf{H}] |\mathbf{u}_k^{(0)}\rangle + [\lambda_K - \mathbf{H}_0] |\mathbf{u}_k^{(1)}\rangle \\ &\quad + [\delta_2 \lambda_k \mathbf{N}_0 - \delta_2 \mathbf{H}] |\mathbf{u}_k^{(0)}\rangle + [\delta_1 \lambda_k \mathbf{N}_0 - \delta_1 \mathbf{H}] |\mathbf{u}_k^{(1)}\rangle \\ &\quad + [\lambda_K - \mathbf{H}_0] |\mathbf{u}_k^{(2)}\rangle + \dots \end{aligned} \quad (59)$$

where we have used the renormalization freedom corresponding to operator $\mathbf{N}_0$. The first line must be equal to zero, as well as all other lines. For the first line, we therefore have

$$\lambda_K |\mathbf{u}_k^{(0)}\rangle = \mathbf{H}_0 |\mathbf{u}_k^{(0)}\rangle \quad (60)$$

which shows that the zeroth-order perturbation $|\mathbf{u}_k^{(0)}\rangle$ belongs to $\mathcal{S}_K$, the subspace mapped by the spherical eigenmodes. Let us now first project Eq. (59) into the space $\mathcal{S}_K$, which is the kernel of the operator $[\lambda_K - \mathbf{H}_0]$. We then get from the second line,

$$\delta_1 \lambda_k \mathbf{N}_0 |\mathbf{u}_k^{(0)}\rangle = \mathcal{P}_K \delta_1 \mathbf{H} |\mathbf{u}_k^{(0)}\rangle \quad (61)$$

where $\mathcal{P}_K$ is the projection into $\mathcal{S}_K$. Relation (61) shows that the first-order perturbation in frequency and the zeroth-order in eigenmodes are the eigensolutions of a $2l+1$ dimension eigenproblem. The same applies for the dual mode, therefore:

$$\delta_1 \lambda_k \mathbf{N}_0 |\mathbf{v}_k^{(0)}\rangle = \mathcal{P}_K \delta_1 \hat{\mathbf{H}} |\mathbf{v}_k^{(0)}\rangle \quad (62)$$

By multiplying the third line of Eq. (59) by $\langle \mathbf{v}_k^{(0)} |$ and using (61), we cancel the last term and therefore obtain the second-order frequency perturbation of the singlet k :

$$\begin{aligned} \delta_2 \lambda_k &= \frac{\langle \mathbf{v}_k^{(0)} | \delta_2 \mathbf{H} \mathbf{u}_k^{(0)} \rangle + \langle \mathbf{v}_k^{(0)} | \delta_1 \mathbf{H} [1 - \mathcal{P}_K] \mathbf{u}_k^{(1)} \rangle}{\langle \mathbf{v}_k^{(0)} | \mathbf{N}_0 \mathbf{u}_k^{(0)} \rangle} \\ &= \langle \mathbf{v}_k^{(0)} | \delta_2 \mathbf{H} \mathbf{u}_k^{(0)} \rangle + \langle \mathbf{v}_k^{(0)} | \delta_1 \mathbf{H} [1 - \mathcal{P}_K] \mathbf{u}_k^{(1)} \rangle \end{aligned} \quad (63)$$

where we have used the normalization of the zeroth-order singlets, $\langle \mathbf{v}_{k'}^{(0)} | \mathbf{N}_0 \mathbf{u}_k \rangle$. Let us now multiply Eq. (59) by the projector into a subspace $\mathcal{S}_{K'}$, associated with a different multiplet. We then get the expression of the perturbations in eigenmodes:

$$\mathcal{P}_{K'} |\mathbf{u}_k^{(1)}\rangle = \frac{1}{\lambda_K - \lambda_{K'}} \mathcal{P}_{K'} \delta_1 \mathbf{H} |\mathbf{u}_k^{(0)}\rangle \quad (64)$$

$$\begin{aligned} \mathcal{P}_{K'} |\mathbf{u}_k^{(2)}\rangle &= \frac{1}{\lambda_K - \lambda_{K'}} [-\mathcal{P}_{K'} [\delta_1 \lambda_k \mathbf{N}_0 - \delta_1 \mathbf{H}] |\mathbf{u}_k^{(1)}\rangle \\ &\quad + \mathcal{P}_{K'} \delta_2 \mathbf{H} |\mathbf{u}_k^{(0)}\rangle + \mathcal{P}_{K'} \delta_1 \mathbf{H} |\mathbf{u}_k^{(1)}\rangle] \end{aligned} \quad (65)$$

The last missing terms are the projection of the eigenmode perturbations inside the perturbed space $\mathcal{S}_K$. As shown by Lognonné (1991), this term appears in the cancellation of the bracket product of (59) with a singlet k' inside the same multiplet as singlet k , which gives

$$\begin{aligned} 0 &= \langle \mathbf{v}_{k'} | [\lambda_k - \mathbf{H}] |\mathbf{u}_k\rangle \\ &= \langle \mathbf{v}_{k'}^{(0)} | [\lambda_K - \mathbf{H}_0] |\mathbf{u}_k^{(0)}\rangle + \langle \mathbf{v}_{k'}^{(1)} | [\lambda_K - \mathbf{H}_0] |\mathbf{u}_k^{(0)}\rangle \\ &\quad + \langle \mathbf{v}_{k'}^{(0)} | [\lambda_K - \mathbf{H}_0] |\mathbf{u}_k^{(1)}\rangle + \langle \mathbf{v}_{k'}^{(0)} | [\delta_1 \lambda_k \mathbf{N}_0 - \delta_1 \mathbf{H}] |\mathbf{u}_k^{(0)}\rangle \\ &\quad + \langle \mathbf{v}_{k'}^{(1)} | [\lambda_K - \mathbf{H}_0] |\mathbf{u}_k^{(1)}\rangle + \langle \mathbf{v}_{k'}^{(1)} | [\delta_1 \lambda_k \mathbf{N}_0 - \delta_1 \mathbf{H}] |\mathbf{u}_k^{(0)}\rangle \\ &\quad + \langle \mathbf{v}_{k'}^{(0)} | [\delta_1 \lambda_k \mathbf{N}_0 - \delta_1 \mathbf{H}] |\mathbf{u}_k^{(1)}\rangle - \langle \mathbf{v}_{k'}^{(0)} | \delta_2 \mathbf{H} |\mathbf{u}_k^{(0)}\rangle \end{aligned} \quad (66)$$

Using the orthogonality between the zeroth-order singlets $|\mathbf{u}_k^{(0)}\rangle$ and decomposing each perturbation into its parts inside and perpendicular to the subspace $\mathcal{S}_K$,

$$|\mathbf{u}_k^{(1)}\rangle = \mathcal{P}_K |\mathbf{u}_k^{(1)}\rangle + \sum_{K' \neq K} \mathcal{P}_{K'} |\mathbf{u}_k^{(1)}\rangle \quad (67)$$

we then rewrite Eq. (61), and with the help of relations (59), (61), (62), and (63), respectively, we obtain

$$\begin{aligned} 0 &= \langle \mathbf{v}_{k'} | [\lambda_k - \mathbf{H}] |\mathbf{u}_k\rangle \\ &= 0 + 0 + 0 + 0 + \langle \mathbf{v}_{k'}^{(0)} | \delta_1 \mathbf{H} \Delta \delta_1 \mathbf{H} |\mathbf{u}_k^{(0)}\rangle - \langle \mathbf{v}_{k'}^{(0)} | \delta_1 \mathbf{H} \Delta \delta_1 \mathbf{H} \mathbf{u}_k^{(0)} \rangle \\ &\quad + \left[(\delta_1 \lambda_k - \delta_1 \lambda_{k'}) \langle \mathbf{v}_{k'}^{(0)} | \mathbf{u}_k^{(1)} \rangle - \langle \mathbf{v}_{k'}^{(0)} | \delta_1 \mathbf{H} \Delta \delta_1 \mathbf{H} \mathbf{u}_k^{(0)} \rangle \right] \\ &\quad - \langle \mathbf{v}_{k'}^{(0)} | \delta_2 \mathbf{H} \mathbf{u}_k^{(0)} \rangle \end{aligned} \quad (68)$$

where

$$\Delta = \sum_{K' \neq K} \frac{1}{\lambda_K - \lambda_{K'}} \mathcal{P}_{K'}$$

This finally gives a first expression for the first-order perturbation inside the multiplet K :

$$\begin{aligned} \langle \mathbf{v}_{k'}^{(0)} | \mathbf{u}_k^{(1)} \rangle &= \frac{1}{\delta_1 \lambda_k - \delta_1 \lambda_{k'}} \left[\langle \mathbf{v}_{k'}^{(0)} | \delta_1 \mathbf{H} \Delta \delta_1 \mathbf{H} \mathbf{u}_k^{(0)} \rangle + \langle \mathbf{v}_{k'}^{(0)} | \delta_2 \mathbf{H} \mathbf{u}_k^{(0)} \rangle \right] \end{aligned} \quad (69)$$

The difference in frequency between two singlets can be as small as a few micro-Hertz and expression (69) therefore leads to very large amplitudes for the first-order perturbation of the eigenmode inside the multiplet K . A similar problem can be found in quantum mechanics (Landau and Lifschitz, 1965).

This is a source of numerical errors and leads practically to the divergence of the perturbation sequence. A perturbation path such that the first-order perturbation of the eigenmode is orthogonal to the subspace K must therefore be chosen, which implies cancellation of the right part of (64). As shown by Lognonné and Romanowicz (1990a), the perturbation theory can then be practically iterated if the iterations are orthogonal to the subspace K . The zeroth-order eigenmode $|\mathbf{u}_k^{(0)}\rangle$ therefore contains all the perturbations in the subspace $\mathcal{S}_K$. This implies, from relations (56) and (69) choosing the perturbation path such that

$$\begin{aligned} \langle \mathbf{u}_{k'}^{(0)} | [\delta_2 \mathbf{H} + \delta_1 \mathbf{H} \Delta \delta_1 \mathbf{H}] | \mathbf{u}_k^{(0)} \rangle &= 0 \\ \delta \mathbf{H}(\lambda_K) + \delta_1 \lambda_k \frac{\partial \delta \mathbf{H}}{\partial \lambda}(\lambda_K) - \delta_1 \mathbf{H} - \delta_2 \mathbf{H} &= 0 \end{aligned} \quad (70)$$

Let us now take the orthogonality relation (35). We can develop this relation with the perturbation sequence, and get, to the first order,

$$-2\sigma_K \langle \mathbf{v}_{k'}^{(0)} | \frac{\partial \mathbf{H}}{\partial \lambda}(\lambda_K) | \mathbf{u}_k^{(0)} \rangle + \langle \mathbf{v}_{k'}^{(1)} | \mathbf{u}_k^{(0)} \rangle + \langle \mathbf{v}_{k'}^{(0)} | \mathbf{u}_k^{(1)} \rangle + \dots \quad (71)$$

This allows us to get the first-order path $\mathbf{N}_0$ and $\delta_1 \mathbf{H}$ of the sequence of perturbation operators, namely:

$$\begin{aligned} \mathbf{N}_0 &= -\mathcal{P}_K \frac{\partial \mathbf{H}}{\partial \lambda} \mathcal{P}_K \\ \delta_1 \mathbf{H} &= \delta \mathbf{H}(\lambda_K) + \mathcal{P}_K \delta \mathbf{H} \Delta \delta \mathbf{H} \mathcal{P}_K \\ \delta_2 \mathbf{H} &= -\mathcal{P}_K \delta \mathbf{H} \Delta \delta \mathbf{H} \mathcal{P}_K \end{aligned}$$

where we have omitted the dispersion correction. Lognonné (1991) gives the expression of the second- and third-order perturbation paths. The final expressions for the perturbations are then summarized in Table 7, with detailed expressions from

Lognonné (1991). It is noteworthy that the second-order perturbation in the squared frequency cancels, so that all the frequency perturbation is included in the isolated multiplet eigenvalue up to second order.

9. Kernels and Computation of Splitting Matrices

All previous expressions need the computation of the coupling matrices expressing the coupling between two singlets of the reference model. As an example, this is the case of the first-order perturbation, which can be rewritten as

$$\begin{aligned} |\mathbf{u}_k^{(1)}\rangle &= \Delta \delta \mathbf{H} |\mathbf{u}_k^{(0)}\rangle \\ &= \sum_{K' \neq K} \frac{1}{\lambda_K - \lambda_{K'}} \sum_{m', m} |l', m', n'\rangle \langle l', m', n' | \delta \mathbf{H} | l, m, n \rangle \langle l, m, n | \mathbf{u}_k^{(0)} \rangle \end{aligned} \quad (72)$$

where the multiplets $K = (n, l)$ and $K' = (n', l')$ have dimensions $2l' + 1$ and $2l + 1$ and where $|l, m, n\rangle$ are the SNREI or SNRAI singlets, associated with a symmetric eigenproduct and with self-dual modes. The coupling matrix between the multiplets K and K' has dimension $(2l' + 1) \times (2l + 1)$ and can be divided into three parts, namely, for the coupling terms between two singlets $k = (n, l, m)$ and $k' = (n', l', m')$:

$$\begin{aligned} \langle l', m', n' | \delta \mathbf{H} | l, m, n \rangle &= H^{kk'} \\ &= H^{kk'(\text{ell})} + H^{kk'(\text{rot})} + H^{kk'(3D)} \end{aligned} \quad (73)$$

where $H^{kk'(\text{ell})}$, $H^{kk'(\text{rot})}$ and $H^{kk'(3D)}$ are respectively the ellipticity, rotation, and lateral variation contributions. Assuming a rotating Earth in hydrostatic equilibrium, the coupling terms $[H^{kk'(\text{ell})} + H^{kk'(\text{rot})}]$ are nonzero only for $m' = m$ and can be expressed as a second-order polynomial of m (Dahlen, 1968).

TABLE 7 Zero-, first-, and second-order expressions of the perturbations in eigenmode and eigenfrequency. The equivalent frequency perturbation, to the second order is given by $\delta\sigma_k = \frac{\delta_1 \lambda_k}{2\sigma_K} - \frac{\delta_1 \lambda_k^2}{8\sigma_K^3}$

Eigenfrequency and Direction of Perturbation in K	
Eigenproblem	$\delta_1 \lambda_k \mathbf{N}_0 \mathbf{u}_k^{(0)} \rangle = \mathcal{P} \delta_1 \mathbf{H} \mathbf{u}_k^{(0)} \rangle$
Eigenoperators	$\mathcal{P} \delta_1 \mathbf{H} \mathcal{P} = \mathcal{P} [\delta \mathbf{H} + \delta \mathbf{H} \Delta \delta \mathbf{H} + \delta \mathbf{H} \Delta \delta \mathbf{H} \Delta \delta \mathbf{H}] \mathcal{P}$
	$\mathbf{N}_0 = \mathcal{P} \left[\mathbf{I} - \frac{\mathbf{B} + \partial_\sigma \mathbf{A}(\sigma_K)}{2\sigma_K} + \delta \mathbf{K} + \delta \mathbf{H} \Delta^2 \delta \mathbf{H} + \delta \mathbf{H} \Delta \left[\delta \mathbf{K} - \frac{\mathbf{B} + \partial_\sigma \mathbf{A}(\sigma_K)}{2\sigma_K} \right] + \left[\delta \mathbf{K} - \frac{\mathbf{B} + \partial_\sigma \mathbf{A}(\sigma_K)}{2\sigma_K} \right] \Delta \delta \mathbf{H} \right] \mathcal{P}$
	$\delta_2 \lambda_k = 0$
Coupling Terms	
First-order	$ \mathbf{u}_k^{(1)}\rangle = \Delta \delta \mathbf{H} \mathbf{u}_k^{(0)}\rangle$
Second-order	$ \mathbf{u}_k^{(2)}\rangle = \frac{\delta_1 \lambda_k}{2\sigma_K} \Delta [\mathbf{B} + \partial_\sigma \mathbf{A}(\sigma_K) - 2\sigma_K \delta \mathbf{K} - 2\sigma_K \mathbf{K}_0 \Delta \delta \mathbf{H}] \mathbf{u}_k^{(0)} \rangle + \Delta \delta \mathbf{H} \Delta \delta \mathbf{H} \mathbf{u}_k^{(0)} \rangle$

The self-coupling part can be expressed as

$$H^{kk(\text{ell})} + H^{kk(\text{rot})} = a + bm + cm^2 \quad (74)$$

where a, b, c are given by (Dahlen and Smith, 1975). The last term includes the effect of the departure from sphericity in the structure,

$$H^{kk(3D)} = \langle l', m', n' | \delta \mathbf{A} | l, m, n \rangle \quad (75)$$

This matrix is a linear expression of the structure and may be linearized with respect to the topography of boundaries. If volumetric perturbations are described in term of complex spherical harmonics,

$$\delta p(r, \theta, \phi) = \sum_{s,t} \delta p_s^t(r) Y_s^t(\theta, \phi) \quad (76)$$

where p can be the density ρ , the bulk modulus κ , or the shear modulus μ , and if the same is applied for the topography of boundaries,

$$\delta h_i(\theta, \phi) = \sum_{s,t} \delta h_{is}^t Y_s^t(\theta, \phi) \quad (77)$$

where $\delta h_i(\theta, \phi)$ is the topography of the i th boundary at radius r_i , the matrix can therefore be developed from the separation of variables as

$$H^{kk'} = \sum_s {}^t \gamma_{ll'}^{mm'} {}_{KK'} C_s^t \quad (78)$$

where

$${}^t \gamma_{ll'}^{mm'} = \int dS \bar{Y}_{l'}^m Y_l^m \quad (79)$$

and

$$\begin{aligned} {}_{KK'} C_s^t = \int_0 \left[{}_{KK'} R_s(r) \delta \rho_s^t(r) + {}_{KK'} K_s(r) \delta \kappa_s^t(r) \right. \\ \left. + {}_{KK'} M_s(r) \delta \mu_s^t(r) \right] r^2 dr - \sum_i r_i^2 h_{is}^t {}_{KK'} B_s(r_i) \end{aligned} \quad (80)$$

where the kernels ${}_{KK'} R_s$, ${}_{KK'} K_s$, ${}_{KK'} M_s$ and ${}_{KK'} B_s$ are functions of the radially dependent parts of the eigenfunctions and are given by Woodhouse and Dahlen (1978). ${}_{KK'} C_s^t$ are the so-called structure coefficients and are associated with the vertical integration. $\gamma_{ll'}^{mm'}$ are related to the integration on the sphere of the product between spherical harmonics and are subject to selection rules. In the isolated multiplet case, the expression for ${}^t \gamma_{ll'}^{mm'}$ is

$${}^t \gamma_{ll'}^{mm'} = (-1)^m (2l+1) \left[\frac{2s+1}{4\pi} \right]^{\frac{1}{2}} \begin{vmatrix} l & s & l \\ -m & t & m' \end{vmatrix} \begin{vmatrix} l & s & l \\ 0 & 0 & 0 \end{vmatrix} \quad (81)$$

where the last two terms are the Wigner $3-j$ symbols (Edmonds, 1960).

The splitting matrix in Eq. (75) can also be computed by a direct integration, as shown by Lognonné and Romanowicz (1990a). We recall here this method can be used for

either smooth or rough (Park, 1989, 1990a; Lognonné and Romanowicz, 1990b) models of lateral variations and does not require a development of the structure in spherical harmonics. The lateral variations related to variations in the stiffness tensor correspond to the following splitting matrix:

$$H^{kk'} = \int dS \int r^2 dr D^\alpha \bar{u}_k^\beta e_{\alpha,\alpha'} e_{\beta,\beta'} \delta C^{\alpha'\beta'\gamma'\delta'} e_{\gamma,\gamma'} e_{\delta,\delta'} D^\gamma u_k^\delta \quad (82)$$

where $\delta C^{\alpha'\beta'\gamma'\delta'}$ is the anisotropic perturbation in stiffness tensor. When SNREI modes are used for the description of the splitting matrices, expression (82) can be rewritten as

$$H^{kk'} = \sum_{N,N'} \int dS \bar{Y}_{l'}^{N'm'} \mathcal{N}_{NN'}^{KK'} Y_l^{Nm} \quad (83)$$

where here the kernels are functions of latitude and longitude and are given by Table 8. Note that the software on the attached Handbook CD uses the spectral method described above.

TABLE 8 Expression of the Kernels for expression (83). $E^{\alpha,\beta}$ are the strain tensor component and $C^{\alpha\beta\gamma\delta}$ those of the stiffness tensor. See Phinney and Burridge (1973) and Mochizuki (1986) for the detailed relations. The software included in the attached Handbook CD was developed in this framework, and allows computation of the splitting matrix for any anisotropic and anelastic Earth model

10. Lateral Variation: Normal Mode Synthetics, Observables and Seismograms

The first effect of lateral variations is to split the degenerated eigenfrequencies. The splitting for the model SAW12D of Li and Romanowicz (1996) is shown in Figure 6 for the spheroidal and toroidal fundamental branches. The splitting of normal modes increases with the angular order, as the consequence of both the increased sensitivity of modes to the shallow structure and the stronger lateral variations in the shallow structures. A shift of the mean frequencies of the singlets is also observed, jointly related to a departure of the reference model (here

FIGURE 6 Splitting of the fundamental spheroidal modes (a), and toroidal modes (b), for the model SAW12D of Li and Romanowicz (1996). The continuous line corresponds to the mean frequency, and its deviation from the reference PREM frequency increases with increasing angular order.

PREM) from the mean Earth structure and to the nonlinear effect related to lateral variations.

The amplitude effects are depicted in Color Plate 2 (upper part) for the isolated case and for two singlets of the fundamental mode ${}_0S_{60}$. The effect of lateral variations indeed changes the pattern of the singlets significantly, as compared to the delocalized spherical harmonics. In contrast, the amplitude of the singlets in a 3D Earth is localized along a great circle for which two singlets are associated. They have almost identical frequencies, and the geographical patterns of the first are mainly shifted from the other along the great circle. This pattern corresponds to a closed and oscillating band along a great circle. Dahlen and Henson (1985) and Henson and Dahlen (1986) have shown that all these trajectories correspond to $2l + 1$ local extrema of the phase perturbation along a closed path on the sphere. The higher-order perturbations of the amplitude of eigenmodes produce focusing and defocusing effects along the great circle associated to the singlet, as well as slight departure from the closed shape of the isolated case band (Color plate 2, lower part). In the asymptotic case, this corresponds to a nonclosed trajectory. For normal modes, these effects are the counterpart of the phase delay of the surface wave packets, the focusing/defocusing effects of the surface wave packets, and the off-path departure of polarization.

Let us now focus on how to observe these effects of lateral variations on normal modes, and how to proceed with data inversion for the retrieval of lateral variations of the Earth. The inversion methods of normal modes are separated into two main families.

The first inversion method consists in the extraction from the data of a set of secondary data corresponding to each multiplet, and then of the inversion of these secondary data for the retrieval of the structure. Let us first illustrate this method, by considering only one multiplet in a perfectly bandpassed seismogram around the frequency σ_K :

$$s(t) = \sum_{m=-l,+l} \langle \mathbf{R} | \mathbf{u}_m \rangle e^{i\sigma_m t} \langle \mathbf{v}_m | \mathbf{S} \rangle \quad (84)$$

where $|\mathbf{u}_m\rangle$, $\langle \mathbf{v}_m|$, and σ_m are the primal, dual amplitudes and eigenfrequency for the singlet m , respectively. Note here that m no longer corresponds to the number of nodes in longitude but can be used as a ranking of the frequency.

In the frequency domain, each of the singlets corresponds to a spectral peak with a minimum width at half power amplitude of ω_K/Q where Q is the quality coefficient of the modes. For the high- Q , very low-order modes, the first and most powerful method is the direct measurement of the frequency of all singlets. For these modes, indeed, the frequency spacing between the singlets is large enough for its resolution, and several peaks can be observed on the data. Several powerful methods were developed for this purpose (Lindberg and Park, 1987; Park *et al.*, 1987). For modes with a higher angular order, Q is lower and the relative frequency spacing between

two successive singlets is also reduced: the singlets become unresolved. The contribution of all the singlets from a multiplet n, l can, however, be expressed by using the mean frequency of the multiplet as a carrier:

$$\sum_{m=-l, +l} \langle \mathbf{R} | \mathbf{u}_m \rangle e^{i\sigma_m t} \langle \mathbf{v}_m | \mathbf{S} \rangle = A(t) e^{i\sigma_\kappa t} \quad (85)$$

where $A(t)$ is a slow amplitude modulation function crystalizing all the 3D perturbations and defined as

$$A(t) = \sum_{m=-l}^{m=l} \langle \mathbf{R} | \mathbf{u}_m \rangle e^{i\delta\sigma_m t} \langle \mathbf{v}_m | \mathbf{S} \rangle \quad (86)$$

For a spherical Earth, this function is a constant, and for the short-time approximation it can be expressed as

$$A(t) = \left[\sum_{m=-l}^{m=l} u_m + it \sum_{m=-l}^{m=l} u_m \delta\sigma_m - \frac{t^2}{2} \sum_{m=-l}^{m=l} u_m \delta\sigma^2 \right] = u_0 e^{i\delta\sigma t} e^{-\beta t^2/2} \quad (87)$$

where $u_m = \langle \mathbf{R} | \mathbf{u}_m \rangle \langle \mathbf{v}_m | \mathbf{S} \rangle$ and

$$u_0 = \sum_{m=-l}^{m=l} u_m, \quad \delta\sigma = \frac{1}{u_0} \sum_{m=-l}^{m=l} u_m \delta\sigma_m, \quad (88)$$

$$\beta = \frac{1}{u_0} \sum_{m=-l}^{m=l} u_m (\delta\sigma_m^2 - \delta\sigma^2)$$

u_0 is the amplitude of the normal mode at the initial time and $\delta\sigma$ is called the local frequency of the mode (Jordan, 1978; Dahlen, 1979). β corresponds to a scattering constant. This shows that the effect of lateral heterogeneities is complex, and consists of

- (i) a perturbation of the initial amplitude and a slow change of the latter with time, and
- (ii) a perturbation of the mean frequency of the peak, which will depend on the excitation of the singlets and therefore the source and receiver.

The two effects above are associated with the main secondary data easily extracted from the normal mode peaks, namely, their initial amplitude and mean frequency. These secondary data can also be computed more directly by asymptotic theory (Jordan, 1978; Romanowicz and Roul, 1986; Park, 1987; Pollitz, 1990). For the fundamental mode, the statistical distribution of the frequency of resonant peaks typically shows a splitting of several per mile (0.1–0.5%). The local frequency depends on the position of the source and receiver, as well as on the source mechanism. In the isolated multiplet hypothesis and asymptotic limit, however, it is equal to the integrated frequency shift along the great circle, and therefore gives information on the shape of lateral variations (Fig. 7). The second-order effects are the exponential decay of the mode and the time variation of the amplitude associated with β , which immediately shows the difficulty inherent in any attenuation study.

FIGURE 7 Map of the local frequency for the mode ${}_0S_{25}$ (Roul and Clévéde, 2000). Relative deviations of the frequencies (%): ◇, $d\omega/\omega = -0.5\%$; +, $d\omega/\omega = +0.5\%$.

For longer times, the short-time approximation is no longer valid. Attempts to develop alternative secondary data, such as a time-varying local frequency (Smith and Masters, 1989) or a spline expression for the modulation function (Nawab and Lognonné, 1994), have been proposed. Note here that a spline interpolation is also used in the software proposed for the computation of seismograms in the aspherical Earth. More sophisticated methods were also developed, allowing a direct inversion from the data of the structure coefficients described in relation (78). Numerous studies of normal mode observations were therefore performed for the retrieval of these structure coefficients, on the lower part of the seismic spectrum, up to around 5 mHz, where the spectral peaks are fairly well isolated. Two techniques to estimate the c_s^l can be distinguished: “singlet stripping” and “spectral fitting.”

In the singlet stripping procedure (Gilbert, 1971; Buland *et al.*, 1979; Ritzwoller *et al.*, 1986), observed data (narrow-band) spectra are summed with appropriate weights in order to enhance a target singlet within a given multiplet. This technique works under the assumption that the singlets are sensitive only to axisymmetric structure (i.e., $l=0$). This assumption appears to be robust for low harmonic degree, high- Q multiplets (Ritzwoller *et al.*, 1986; Widmer *et al.*, 1992a).

In the spectral fitting technique (Ritzwoller *et al.*, 1986, 1988; Giardini *et al.*, 1987, 1988; Li *et al.*, 1991a,b; Widmer *et al.*, 1992a,b; Tromp and Zankerka, 1995; He and Tromp, 1996) the dependence of displacement on the structure coefficients and the frequency perturbation is linearized, and the $_{kk'}c_s^l$ are estimated by iteratively fitting the spectra in the frequency band surrounding the multiplet. In this case, no a priori knowledge on the aspherical structure is required and non-linearity is taken into account by iterative procedure. Smith and Masters (1989) developed the technique to incorporate uncoupled hybrid multiplets, and more recently a generalized spectral fitting technique (Resovsky and Ritzwoller, 1995, 1998) has been developed incorporating inter-multiplet coupling. This extension of the spectral fitting technique allows inversion for odd-degree structure. This method has been used to produce a degree-8 shear velocity mantle model using normal mode observations below 3 mHz (Resovsky and Ritzwoller, 1999).

The second type of inversion is the direct inversion, which directly extracts the structure from the waveform or waveform packet synthesized by normal mode summations. The early works were based on a summation of SNREI modes with a phase correction computed by ray theory (e.g., Woodhouse, 1983; Woodhouse and Dziewonski, 1984), following theory described by Woodhouse and Wong (1986).

Using the SNREI modes for the computation of synthetic seismograms, asymptotic methods have provided better modeling of effects such as focusing or concentration of body-wave sensitivity (e.g., Romanowicz, 1987; Li and Tanimoto, 1993). Inversions (Li and Romanowicz, 1995, 1996) with these theories provided new and improved tomographic models.

More sophisticated methods were then developed, with the computation of seismograms from aspherical normal modes, as described above. Such methods can indeed be used for the computation of seismograms in rather sophisticated models: Rough models (Lognonné and Clévéde, 1997), anisotropic models, and anelastic models. Compared to perturbation theories, alternative methods can also be used in the computation of the normal modes necessary for the summation, such as variational methods (Morris *et al.*, 1987; Hara *et al.*, 1991). The theory for the computation of the Fréchet derivatives was also developed, either in the framework of perturbation theory (Clévéde and Lognonné, 1996) or for variational theory (Geller and Ohminato, 1994).

Only one attempt has been done to perform a direct structure inversion from such complete waveforms, by Hara *et al.* (1993). Clévéde *et al.* (2000), however, confirmed that the impact of the theory errors in the tomographic models already developed can be quite significant, and will justify the stronger computational effort in the future.

11. Conclusion and Perspectives

Almost 40 years after their first observations, the results published on normal modes have clearly demonstrated that observing and inverting the normal modes of a planet is one of the most powerful methods for recovering its internal structure. It is also the only way to get from seismic data a direct sensitivity to density, including lateral variations (Tanimoto, 1991), as all other waves are sensitive mostly to the seismic velocities. The theory is now very mature, and almost completely described, with only a few last refinements missing, such as the nonlinear effect of the shape of discontinuities and boundary conditions. Very likely, the present models and theories are reaching a challenging maturity and give a satisfactory explanation of the frequency-related features of the normal modes. Amplitude-related features, including attenuation, are much less well explained.

In parallel, the already developed theories and the numerical software, such as those included on the attached Handbook CD (see, Chapter 85.16, by Clévéde and Lognonné), give the opportunity to use normal modes as one of the most powerful tools for the computation of seismograms in a complex and realistic Earth. The complete sequence, with first the mode computation of the SNREI, then the mode computation for an aspherical, anisotropic, and attenuating Earth, and finally the normal mode summation for the retrieval of long-period seismometers, is therefore provided. We can therefore expect in the near future the elaboration of a new generation of tomographic models with waveform modeling from fully coupled normal mode summations.

Future space missions to telluric planets of the solar system can also give us the opportunity to rediscover the excitement of the 1960s, but now with the first observations of normal

modes of other planets. For the time being, only computations for speculative a priori structure have been performed. For the Moon, modes have been computed in different a priori models for the structure by Carr and Kovach (1962), Takeuchi *et al.* (1961), Saito *et al.* (1966), Bolt and Derr (1969), and Derr (1969b). Similarly, normal modes have been computed for Mars by Bolt and Derr (1969) and for Venus by Okal and Anderson (1978), Lognonné and Mosser (1993), Lognonné *et al.* (1996), and Sohl and Spohn (1997). All these studies demonstrate the high potential of observing normal modes. However, with the absence of strong tectonics on the Moon, the instrument noise will very likely be too high for their detection. Mars, as shown by Lognonné *et al.* (1996), may have a seismic activity compatible with normal mode detection, and moreover has an atmosphere allowing a permanent excitation of normal modes (Kobayashi and Nishida, 1998). Their detection will be one of the scientific objectives of the seismic experiment (Lognonné *et al.*, 2000) to be deployed by the NetLander mission, expected for launch in 2007 (Harri *et al.*, 1999; Lognonné *et al.*, 2000).

Acknowledgments

This work was sponsored by several CNRS/INSU grants, including ASP Tomographie, Programme Intérieur de la Terre, and Programme National des Risques Naturels. We thank J. Artru for her contribution, as well as B. Romanowicz, F. Pollitz, and an anonymous reviewer for their comments and corrections. This is IGP contribution 1708.

Inversion of Surface Waves: A Review

Barbara Romanowicz

University of California, Berkeley, California, USA

1. Introduction

In what follows, we attempt to review progress made in the last few decades in the analysis of teleseismic and regional surface wave data for the retrieval of earthquake source parameters and global and regional Earth structure. This review is by no means exhaustive. We will rapidly skip over the early developments of the 1950s and 1960s that led the foundations of normal mode and surface wave theory as it is used today. We will not attempt to provide an exhaustive review of the vast literature on surface wave measurements and the resulting models, but rather focus on describing key theoretical developments that are relevant and have been applied to inversion. Since surface wave theory is closely related to that of the Earth's normal modes, we will discuss the latter when appropriate. However, we make no attempt to extensively review normal mode theory, as this subject is addressed in a separate contribution (see Chapter 10 by Lognonné and Clévéché).

2. Background

Most of the long-period energy (periods greater than 20 s) generated by earthquakes and recorded at teleseismic distances propagates as surface waves. Most clearly visible on long-period seismograms are the successive, Earth-circling, dispersed wave trains of the fundamental mode. For moderate size earthquakes recorded at teleseismic distances ($M \sim 5.5$), only the surface waves propagating along the direct great circle path between the epicenter and the station have significant signal-to-noise ratio, mostly between 20 and 100 s period, and the dispersive and attenuative properties of these wave trains have been used extensively, since the 1950s to infer crust and upper mantle structure in different regions of the Earth. For earthquakes of magnitude 7 or larger, successive Earth-circling surface wave trains can be followed for many hours (Fig. 1), and are then either analyzed individually or combined to

FIGURE 1 Example of vertical component record showing many Earth-circling mantle Rayleigh wave trains over a time window of 14 h. This record was recorded at station CMB of the Berkeley Digital Seismic Network (BDSN) and corresponds to a channel with a sampling rate of 1 sample/sec. The earthquake is shallow and the epicentral distance $\Delta = 109.7^\circ$. Because the distance is close to 90° the wave packets corresponding to even and odd order trains are well separated from each other. (Courtesy of Joseph Durek and Lind Gee.)

produce a spectrum of the Earth's free oscillations by Fourier analysis of long time-series.

Most studied are fundamental mode Rayleigh waves, which correspond to P – SV energy and have elliptical particle motions in the vertical plane containing the direction of propagation. These waves are well recorded on the quieter vertical component seismographs (Fig. 2). On the other hand, Love waves, which carry SH energy, and are polarized horizontally in a direction perpendicular to the direction of propagation, require rotating the two horizontal records to extract the transverse component of motion. Love wave studies have suffered,

FIGURE 2 Three-component seismograms observed at station CMB for a shallow earthquake at a distance of $\Delta=88.7^\circ$. The horizontal components have been rotated to the longitudinal and transverse directions, clearly exhibiting fundamental mode Love and Rayleigh waves on the transverse and vertical/longitudinal components, respectively. (Courtesy of Joseph Durek and Lind Gee.)

especially in the early days of analog recordings, from the more complex data processing required, and from the higher levels of background noise on horizontal components at long periods, due primarily to the influence of atmospheric pressure variations, inducing ground tilts. Fundamental mode Love and Rayleigh waves are generally well separated from other phases on the seismograms, and well excited by shallow, crustal earthquakes, while overtones travel at higher group velocities, appear as packets of mixed overtones (e.g., X phases, Jobert *et al.*, 1977), and are better excited by deeper earthquakes (Fig. 3).

Surface waves recorded at teleseismic distances contain information about both the characteristics of the earthquake source and the structure of the Earth along the source station path. Separating these two effects has been one of the long-standing challenges faced by seismologists.

Studies of the structure of the crust and upper mantle progressed rapidly in the 1950s and early 1960s, as the tools to measure group and phase velocities, and interpret them in terms of layered mantle and crust models, became readily available (e.g., Ewing *et al.*, 1957; Brune *et al.*, 1961a,b; Alsop, 1963). In these studies, source effects were generally eliminated by considering propagation between two or more stations aligned along the same great circle path, or, at longer periods, observation of consecutive Earth-circling wave trains at the same station. On the other hand, in early studies of earthquake sources, propagation effects were assumed to be known, and amplitudes were “equalized” to obtain the source radiation pattern and infer information about the fault orientation (e.g., Aki, 1960) and its directivity (Alterman *et al.*,

FIGURE 3 Example of longitudinal component seismogram recorded at IRIS/GSN station SUR showing the arrivals of multiply reflected body wave phases forming a higher-mode Rayleigh wave train in front of the fundamental mode (R_1). The Airy phase, corresponding to the group velocity minimum around 230 sec, is well visible in the R_1 train. The event occurred on 14 Jan. 1997 in southern Bolivia, at a depth of 276 km. The epicentral distance is 8419 km. The seismogram has been bandpass filtered with cut-off frequencies at 35 and 400 sec. (Courtesy of Yuancheng Gung.)

1959; Ben-Menahem, 1961; Kanamori, 1970). At that time, the theoretical formulation for the excitation of surface waves and normal modes of the Earth was developed (Sato *et al.*, 1962; Harkrider, 1964; Haskell, 1964), much stimulated by the occurrence of the great Chilean earthquake of 22 May 1960, and more quantitative studies of the effects of the earthquake source on spectra of surface waves followed. The association of a normal mode formalism (e.g., Gilbert, 1971) to compute dispersion and excitation of surface waves (and complete seismograms) with a moment tensor formalism to describe the earthquake source (e.g., Backus and Mulcahy, 1976; Mendiguren, 1977) has led to the present-day commonly used expressions and to a rapid development of source studies based on surface waves in the 1980s. A computational method (Takeuchi and Saito, 1972), following the theoretical approach of Saito (1967) based on Runge-Kutta matrix integration, has long been the main reference for the practical calculation of excitation for surface waves and normal modes in laterally homogeneous, elastic, flat or spherical Earth models. Later, different schemes, using different mathematical approaches (variational method) were developed (Wiggins, 1976; Buland and Gilbert, 1984). Today, another widely used code for spherical geometry and efficient to relatively short periods (10 s) is based on a propagator matrix approach, in which minors of sets of solutions are used (Gilbert and Backus, 1966; Woodhouse, 1980a, 1988).

These theoretical advances were first applied to the analog data of the World Wide Standard Seismic Network (WWSSN) accumulated in the 1960s and 1970s. The IDA (International Deployment of Accelerometers) network, established in the mid-1970s (Agnew *et al.*, 1976), provided the first long-period digital data, along with several stations installed and operated by the French (Jobert and Roullet, 1976). The digital recording greatly facilitated the simultaneous analysis of many records, paving the way for large-scale tomographic studies of global structure and systematic teleseismic source studies. A major drawback, however, was the limited dynamic range of the IDA instruments, so that first-arriving low-frequency R_1 and G_1 wave trains would saturate for large earthquakes. This problem disappeared in the 1980s with the deployment by France of the high dynamic range, digital broadband GEO-SCOPE network (Romanowicz *et al.*, 1984, 1991) and by the United States of the IRIS Global Seismic Network (e.g., Smith, 1986), gradually complemented by many broadband stations contributed by other countries through the Federation of Digital Seismic Networks (FDSN), which, starting in 1986, established high-level standards for broadband seismic sensors, recording systems, and data formats (e.g., Romanowicz and Dziewonski, 1986). The accumulation of high-quality data from numerous broadband stations has greatly contributed to the successes of global tomography and source moment tensor studies of the last 15 years.

3. Source Studies Using Surface Waves

To obtain the frequency spectrum of a single mode surface wave train from the expression of a seismogram obtained by summation of normal modes on a spherically symmetric Earth, one uses Poisson's formula (e.g., Gilbert, 1976; Aki and Richards, 1980), which decomposes the modes into infinite trains of propagating surface waves traveling in opposite directions around the Earth. In this process, a high-frequency approximation is used, in which the phase velocity of a surface wave is related to the corresponding normal mode frequency by Jeans's formula:

$$C(\omega) = \frac{a\omega_l}{l + 1/2} \quad (1)$$

where l is the angular order of the mode and ω_l its eigenfrequency, and a is the radius of the Earth. In this high-frequency approximation, the surface waves propagate along the great circle path between the epicenter and the station and are sensitive to structure only along this great circle.

The most widely used theoretical framework for the interpretation of surface wave data was thus established in the 1970s. It is derived from a normal mode formalism using a high-frequency zeroth-order approximation, and leads to a simple expression for the spectrum of a single mode propagating

surface wave at distance Δ , azimuth θ , and angular frequency ω . Following Kanamori and Stewart (1976), and Nakanishi and Kanamori (1982):

$$U(\Delta, \theta, \omega) = U_s(\theta, \omega)S(\Delta)U_p(\Delta, \theta, \omega)F(\omega, \theta_0)D(\omega)I(\omega) \quad (2)$$

where U_s is the source spectrum, U_p contains propagation effects, I is the instrument response, $S(\Delta)$ the geometrical spreading term, and F and D express the source process as clarified below.

The propagation term U_p can be expressed as (e.g., Romanowicz and Monfret, 1986)

$$U_p(\Delta, \theta, \omega) = \frac{1}{(\sin \Delta)^{1/2}} \exp(i\pi/4) \exp(im\pi/2) \times \exp[-i\omega\Delta/C(\omega, \theta)] \exp[-\eta(\omega, \theta)\Delta] \quad (3)$$

where m denotes the number of polar passages and $C(\omega, \theta)$, $\eta(\omega, \theta)$ are, respectively, the average phase velocity and attenuation coefficient along the source–station path.

The source spectrum U_s is a linear combination of the moment tensor elements M_{ij} of the source. In the notation of Kanamori and Stewart (1976), we have for Rayleigh waves:

$$U_s^R(\theta, \omega) = \frac{1}{3}(S_R + N_R)M_{zz} + \frac{1}{6}(2N_R - S_R)(M_{xx} + M_{yy}) + \frac{1}{2}P_R(M_{yy} - M_{xx})\cos 2\theta - P_RM_{xy}\sin 2\theta + iQ_R(M_{xz}\cos \theta + M_{yz}\sin \theta) \quad (4)$$

where N_R , S_R , P_R , Q_R are the excitation functions, which are nonlinear functions of ω and of the depth h of the source.

Likewise, for Love waves:

$$U_s^L(\theta, \omega) = P_L\left[\frac{1}{2}(M_{xx} - M_{yy})\sin 2\theta - M_{xy}\cos 2\theta\right] + iQ_L(-M_{xz}\sin \theta + M_{yz}\cos \theta) \quad (5)$$

with depth-dependent excitation functions P_L, Q_L . $D(\omega)$ expresses the delay τ_D of the main faulting from the initial break (e.g., Nakanishi and Kanamori, 1982):

$$D(\omega) = \exp(-i\omega\tau_D) \quad (6)$$

and $F(\omega, \theta_0)$ expresses the directivity term arising from the propagation of rupture. Ben Menahem (1961) derived an approximate expression for F in the case of unilateral faulting, which has been shown to be exact if an equatorial coordinate system is used (Dziewonski and Romanowicz, 1977):

$$F(\omega, \theta_0) = \frac{\sin X}{X} \exp(-iX) \quad (7)$$

where

$$X = \frac{\omega L}{2V} - \frac{\omega L}{2C} \cos(\theta - \theta_0) \quad (8)$$

and L is the length of fault, C is the average phase velocity at frequency ω , V is the rupture velocity, and θ_0 is the azimuth of the rupture direction with respect to the fault strike.

As seen from Eqs. (2) to (8), fundamental mode surface wave spectra contain information about the source moment tensor, source depth (centroid), source process time, and, under favorable circumstances for very large earthquakes, source directivity. However, propagation effects U_p have to be known or effectively eliminated.

In order to correct for propagation, different approaches need to be taken depending on the size of the earthquake and period range considered. At very long periods ($T > 180$ sec) and for large earthquakes ($M > 6.5$), propagation effects can be accounted for approximately in the framework of a spherically symmetric reference Earth model. At shorter periods and for smaller earthquakes, corrections on individual source–station paths need to be known much more accurately. We thus discuss these two domains separately.

3.1 Teleseismic Studies of Moderate Size Events ($M \sim 5\text{--}6$)

Today significant efforts are still expended toward surface wave “path calibration,” in particular in the framework of CTBT research (e.g., Stevens and McLaughlin, 2000). However, several methods have been developed to deal with poorly known path effects, with particular applications to the study of moderate earthquakes, for which good signal-to-noise records of 20–100 sec surface waves are obtained at teleseismic distances. In this case, source duration and directivity can generally be neglected, since their effect is significant only at shorter periods. A standard procedure is to use a “reference event,” for which a reliable mechanism has been obtained independently, to obtain path corrections to specific stations. These path corrections are then used to infer source parameters of other neighboring events of interest. Following the approach of Weidner and Aki (1973), Patton (1977) developed an iterative method to infer simultaneously depth, source mechanism, and propagation effects for a group of closely located events observed teleseismically. On the path to a given station, the propagation effects are assumed to be the same for all events. In adjacent steps of the procedure, path effects and source characteristics are alternately improved. In the source improvement step, the linear system in M_{ij} [Eqs. (4) and (5)] is solved successively for different depth values, and a solution is declared corresponding to the depth that provides the best fit to the data in a least-squares sense. The imaginary parts of Eqs. (4) and (5) generally do not contribute to the depth determination, as, for shallow earthquakes, the eigenfunctions corresponding to the moment tensor elements M_{xz} and M_{yz} are very small (and go to zero at the free surface). This also results in poor constraints on these two moment tensor elements for shallow ($h < 20$ km) earthquakes if only fundamental mode surface waves are used.

The method of Patton (1977) is limited by the fact that it requires several earthquakes located in the same area to be well recorded teleseismically at the same set of stations.

Moreover, Aki and Patton (1979) have shown that, in order to obtain reliable moment tensor solutions from data in the period range 20–100 sec, it is necessary to know average phase velocities on source station paths with an accuracy of 0.5%. When path corrections in the phase are inaccurate, the method breaks down because a clear minimum in the residuals/depth curves cannot be defined. On the other hand, because path effects on amplitudes are less coherent, an average- Q model is sufficient if only amplitude data are used (Mendiguren, 1977). Tsai and Aki (1971) first showed how the amplitude spectrum of Rayleigh waves (and to a lesser extent Love waves) contained the signature of depth of source in the period range 10–100 sec, in the form of a “hole” in the spectrum, which appears at a given period for a specific source mechanism. However, when amplitudes only are used, the inverse problem becomes nonlinear in the moment-tensor, requiring the knowledge of a reasonable starting solution.

A procedure that greatly relaxes the constraint of accurate path corrections in the phase was proposed by Romanowicz (1982a), based on the following observation: For a given source and at a given frequency ω_k , the real (α) and imaginary (β) parts in Eqs. (4) and (5) are functions of the azimuth θ only, and can be written in the form

$$\begin{aligned}\alpha(\omega_k, \theta) &= A_k + B_k \cos 2\theta + C_k \sin 2\theta \\ \beta(\omega_k, \theta) &= D_k \cos \theta + E_k \sin \theta\end{aligned}\quad (9)$$

where A_k , B_k , C_k , D_k , and E_k depend on frequency. By virtue of the uniqueness of the Fourier decomposition of continuous functions, at each frequency ω_k , given a set of values of α and β for different azimuths θ , these coefficients are uniquely determined. The Fourier expansions of α and β in azimuth contain other coefficients, of degree $n > 2$, that arise from imperfect knowledge of path corrections. In solving Eqs. (9), these other terms are eliminated. Thus only the very long-wavelength ($n \leq 2$) terms of the phase velocity “map” in the region containing sources and stations need to be known accurately, an increasingly reachable goal today, thanks to improvements in global surface wave tomography.

The inversion procedure thus proceeds in “two steps”: First, Eqs. (9) are solved at a set of frequencies $\omega_1, \dots, \omega_k$, and second, the following system of equations is solved for depth h , searching, as previously, for a minimum in the residuals/depth curve. Thus, for example, for Rayleigh waves:

$$\begin{aligned}A_k &= \frac{1}{2} S_r(\omega, h) M_{zz} \\ B_k &= \frac{1}{2} P_r(\omega, h) (M_{yy} - M_{zz}) \\ C_k &= -P_r(\omega, h) M_{xy} \\ D_k &= Q_r(\omega, h) M_{xz} \\ E_k &= Q_r(\omega, h) M_{yz}\end{aligned}\quad (10)$$

Here we have assumed that there is no volume change at the source so that $\sum_i M_{ii} = 0$ and $M_{xx} + M_{yy}$ is replaced by

$-M_{zz}$ in Eq. (2). While justified for most earthquakes, this assumption needs to be relaxed when a volumetric component of the source is sought. To resolve the latter requires multimode observations, and Eqs. (2) to (8) show that resolving M_{xx} , M_{yy} , and M_{zz} separately involves many trade-offs with structure effects (e.g., Dufumier and Rivera, 1997). Romanowicz (1982a) showed that this procedure allows the determination of accurate source parameters for small events ($M < 5.5$), for which only surface wave observations are available teleseismically, provided one event of larger magnitude is available, with a well-constrained mechanism, in a source region ~ 1500 km in aperture. This method was later extended to the nonlinear inversion of surface wave amplitude data (Romanowicz and Suarez, 1983).

3.2 Global Studies of Large Earthquakes

At very long periods ($150 < T < 320$ sec) and for large earthquakes ($M > 6.5$), spherically symmetric Earth models can be used to correct for propagation effects in the phase of “mantle” waves (as surface waves are called in this period range), and the biases introduced by neglecting lateral heterogeneity are relatively small, except for very shallow events, for which the source phase needs to be known with greater accuracy. In the last 15 years, the availability of global 3D tomographic models of the upper mantle of increasing accuracy has not only facilitated very long-period source studies but has also made it possible to extend the period range to shorter periods (down to ~ 120 sec) and to efficiently make use of alternative methodologies, based on time-domain waveform inversion, that are no longer restricted to the fundamental mode, thus providing more accurate estimation of the source depth. Such a waveform approach was introduced by Dziewonski *et al.* (1981), who combined waveforms of mantle waves at periods greater than 120 sec with waveforms of body waves at periods greater than 80 sec. This forms the basis of a now routine procedure that serves to construct the widely used Harvard centroid moment tensor (CMT) catalog.

The development of methodologies to invert fundamental mode mantle wave data has nevertheless continued, following Kanamori and Given (1981), who showed how the spectra of mantle waves, sampled at only a few frequencies, could be used to rapidly determine moment tensors of large earthquakes, when the depth of the event is known. Romanowicz and Guillemant (1984) extended the approach of Romanowicz (1982a) to show how centroid depth could be accurately determined using mantle waves even in a spherically symmetric reference Earth model. For the size of earthquakes considered here, the source process time (Nakanishi and Kanamori, 1982) cannot be neglected and there can be significant trade-offs with source depth. However, the source process time can be estimated, as a function of frequency, prior to the inversion by computing phase differences between three wave trains at each individual station (e.g., Furumoto,

1979; Furumoto and Nakanishi, 1982). For example, if Rayleigh wave trains R_{2n} , R_{2m+1} and R_{2n+2} are used, with R_{2m+1} traveling in the opposite direction to the two other trains, we have, for the corresponding phases Φ_i :

$$\Phi_{2n} + \Phi_{2m+1} + (n+m)(\Phi_{2n} - \Phi_{2n+2}) + 2\Phi_{\text{instr}} = -\omega\tau + k2\pi \quad (11)$$

where k is an arbitrary integer and the source time τ is defined as [Eqs. (6), (7), and (8)]

$$\tau = \frac{L}{V} + 2\tau_D \quad (12)$$

Expression (11) is independent of structure within the framework of the high-frequency approximation in which it is derived. This procedure requires that at least three mantle wave trains traveling in opposite directions have adequate signal-to-noise ratio, which can be rather restrictive. Romanowicz and Monfret (1986) proposed an approach that requires the availability of only one mantle wave train.

Noting from Eqs. (3) to (9) that, if U_c is the observed spectrum corrected for instrument response and propagation, then,

$$U_c(\theta, \omega)e^{i\Phi_\tau} = U_s(\theta, \omega) = \alpha + i\beta \quad (13)$$

where

$$\Phi_\tau = \frac{\omega\tau}{2 + \delta\phi} \quad (14)$$

$\delta\phi$ is the residual phase shift due to inaccurate propagation corrections in the phase, and α and β are the real and imaginary parts of Eqs. (4) and (5), respectively. For specified, incremental values of $\tau_j, j = 1, \dots, p$ of τ , the system of Eqs. (4) and (5) is solved for different frequencies ω_k , the squared residuals of this inversion for each frequency are summed to obtain a squared residual as a function of τ , and the solution is found for the value of τ corresponding to the minimum value of this residual. The second step of the inversion proceeds as described above [Eqs. (9) and (10)]. Unlike the three-train method of Furumoto and Nakanishi (1982), because of the trade-off with Earth structure as seen in Eq. (14), the determination of the source time by this method depends on the accuracy of the Earth model used, and specifically, on errors in the Earth model that contribute a constant phase shift as a function of azimuth, that is, long-wavelength features. A regionalized global model, such as that of Okal (1977), was shown to be sufficient to obtain stable source time estimates. With the increased precision of currently available 3D tomographic models, this is no longer an issue. This method can be extended to the case of large earthquakes with significant directivity, by including a parameter search over the azimuth θ_0 of the fault and the rupture length L . For very large earthquakes, Kuge *et al.* (1996) showed that source complexity (spatiotemporal changes in the source mechanism) sometimes

needs to be invoked to reconcile source mechanisms obtained separately using Love and Rayleigh waves. The spectral domain inversion of fundamental mode mantle waves was further tested against Earth models and applied to large earthquakes by Zhang and Kanamori (1988a,b), showing generally consistent results with the Harvard CMT solutions. An alternative approach to study the spatiotemporal characteristics of large earthquakes from surface wave data has been proposed by Bukchin (1995), who used a representation of the source in terms of higher-order moments.

3.3 Regional Distance Source Studies

While most of the modern formalism and methodology for intermediate-period surface wave inversion for source parameters was in place by the mid-1980s, they have only been recently adapted to the case of earthquakes observed at regional distances. This has been made possible by the rapid expansion, in the last ten years, of regional broadband networks in seismically active regions, such as, for example, TERRAScope (Thio and Kanamori, 1995) or the Berkeley Digital Seismic Network (BDSN; Romanowicz *et al.*, 1993) in southern and northern California, respectively, MEDNET in the Mediterranean region (Giardini *et al.*, 1993), and also in Japan. In the regional case, target frequent earthquakes have smaller magnitude (generally $M < 4.5$) and the period range of interest is ~ 10 – 60 sec (Fig. 4). Here, an important aspect

is to obtain information about the earthquake source rapidly to guide local emergency response, and this has led to the development of automated procedures (e.g., Pasyanos *et al.*, 1993). The theoretical framework is essentially the same as was developed for teleseismic observations at intermediate (Romanowicz, 1982a) or long periods (Kanamori and Given, 1981; Romanowicz and Monfret, 1986). Some automatic procedures involve the comparison of a spectral domain inversion of fundamental mode surface waves with a time domain complete waveform inversion, at periods longer than 10 sec (e.g., Pasyanos *et al.*, 1993).

With the improvement of global upper mantle models, it is now also possible to extend to smaller magnitudes ($M_W > 4.5$) the time-domain CMT inversion methodology developed by Dziewonski *et al.* (1981), making use of intermediate-period surface waves (Ritsema and Lay, 1993). Arvidsson and Ekström (1998) use a low-pass cutoff at ~ 45 sec and consider the fundamental mode surface waves as traveling waves. The phase is corrected for propagation effects using recent global phase velocity maps.

4. Structure Studies Using Surface Waves

4.1 Fundamental Mode Studies

Fundamental mode surface waves are well suited to study the elastic structure of the crust and upper mantle, which can be deduced from their group and/or phase dispersion properties. They allow the sampling of vast areas of the globe that are otherwise devoid of seismic stations and sufficiently strong earthquake sources, such as the oceans.

It is beyond the scope of this chapter to review the numerous studies that have used surface waves to infer lateral variations of seismic velocities in the crust and upper mantle, since the 1950s and up to this day. Many early studies documented the correlation of seismic velocity variations with surface tectonic features, using regional measurements of phase and group velocities of fundamental mode Love and Rayleigh waves in the period range 20–100 sec (e.g., Knopoff, 1972; Kovach, 1978) or at longer periods (e.g., Toksöz and Anderson, 1966; Dziewonski, 1971; Wu, 1972). Originally, group velocity dispersion was obtained by measuring the times of arrival $t(\omega)$ of peaks and troughs of waves in a dispersed wave train. The time between two successive peaks would give the half period ($T/2 = \pi/\omega$), and the group velocity $U(\omega)$ would be computed as

$$U(\omega) = \frac{X}{t(\omega)} \quad (15)$$

where X is epicentral distance in kilometers and $t(\omega)$ is measured with respect to the earthquake's origin time. Since the early 1970s, the computation of "energy diagrams," as

FIGURE 4 Moment tensor solutions obtained for all earthquakes of magnitude $M_W > 3.5$ in northern California for the period 08/98 to 09/99, using data from the Berkeley Digital Seismic Network. The size of the beachball is proportional to magnitude. (Courtesy of Hrvoje Tkalčić.)

FIGURE 5 Example of group velocity dispersion diagrams obtained for the fundamental Rayleigh wave mode on the vertical record of the Chile M_s 6.8 earthquake of 15 Oct. 1997 at Geoscope station INU, using a multiple filtering approach as perfected in the FTAN method (e.g., Lander, 1989; Levshin *et al.*, 1994). (a) Dispersion diagram before filtering; (b) same after filtering. The group velocity dispersion curve obtained follows the maxima of energy as delineated by the gray scale contours. (c) Corresponding time-domain seismogram before and after variable filtering. The “raw” seismogram is bandpass filtered in the period 50–400 sec. (Courtesy of Boris Bukchin.)

described below, has greatly facilitated group velocity dispersion measurements (e.g., Fig. 5).

On the other hand, phase velocity $C(\omega)$ is obtained from the phase Φ of the Fourier spectrum of a dispersed wave train that has been corrected for the contribution of the source and the instrument [Eq. (2)]:

$$C(\omega) = \frac{X}{t_0 - [\Phi - N - (m/4) - 1/8]/\omega} \quad (16)$$

where t_0 is the start time of the Fourier window with respect to the event’s origin time, m is the number of polar passages, and N is an integer arising from the 2π indeterminacy of the phase. This integer is determined first at long periods to obtain reasonable values of phase velocity compatible with well-constrained global models (e.g., PREM; Dziewonski and Anderson, 1981). It is then successively obtained at decreasing periods in such a way as to obtain a smooth phase velocity curve. This can become a problem at periods shorter than 30 sec, where small variations in phase velocity correspond to rapid cycling of the phase. The source phase also needs to be accurately corrected for.

Most early studies circumvented the issue of separating source and propagating effects by making measurements using the “two-station method,” in which dispersion was measured between two stations approximately aligned with the epicenter on a great circle path, thus eliminating the common source phase. If, in addition, the two stations were located within a relatively homogeneous geological province, such measurements were called “pure path” and led directly to the determination of elastic velocity structure beneath that province. An extension of this method to “many stations” to infer structure beneath an array of stations spanning a geologically homogeneous region was also devised and used extensively in the 1960s (e.g., Knopoff *et al.*, 1967). To access remote regions devoid of stations but with relatively frequent earthquakes of magnitude 5.5 or larger, such as the Tibet Plateau, a “two-event” method was also devised. The success of this approach, which relied on an accurate independent knowledge of the source phase, was only possible under very restrictive conditions. In particular, the alignment of the three points (two epicenters, one receiver) had to be within 3° of the great circle path (e.g., Romanowicz, 1982b).

At longer periods, especially beyond the group velocity minimum at 200–250 sec, fundamental mode dispersion measurements were hampered by interference with higher modes (a problem also in the vicinity of the group velocity maximum around 60 sec), and the fact that the longest-period waves are not sufficiently well dispersed on first-arriving trains. In the early 1970s sophisticated filtering techniques were developed (Dziewonski *et al.*, 1969; Cara, 1973a,b) to isolate a surface wave mode along its group velocity curve (Fig. 5). This approach, later perfected by Levshin and collaborators in the FTAN method (e.g., Lander, 1989; Levshin *et al.*, 1994), involves two steps. In the first step, an “energy diagram” is formed, in which the energy contained in the seismogram is plotted as a function of period and time (i.e., group velocity). The maxima of the 2D diagram thus obtained delineate the group velocity curve of the dispersed surface wave modes present in the seismogram in the time window and frequency window considered. In a second step, the time-domain seismogram is then filtered using multiple filters centered, at each point in time, on the frequency corresponding to the maximum of energy at that time. The possibility of simultaneously inverting group and phase velocity data has been discussed by Yanovskaya and Ditmar (1990).

By allowing the extraction of a mode branch over many consecutive wave trains, these techniques also resulted in better measurements of the spheroidal and toroidal eigenfrequencies for the fundamental and several higher modes (e.g., Jobert and Roullet, 1976). With the advent of digital recording in the mid-1970s and the expansion of global digital long-period and later broadband networks, the processing of the relatively long time-series needed to measure surface waves became much easier and opened the way in the 1980s to large-scale and global studies of upper mantle structure.

Large-scale studies first proceeded according to a regionalization scheme, in which it was assumed that the depth variation of seismic velocities is the same throughout each tectonic province. These studies confirmed and extended to longer periods (and hence larger depths) early results on the age dependence of structure in the oceans (e.g., Forsyth, 1975; Montagner and Jobert, 1983; Nishimura and Forsyth, 1989). The constraint of regionalization was soon relaxed, after Dziewonski *et al.* (1977) introduced the expansion of lateral heterogeneity into a basis of spherical harmonics (applied first, however, to the lower mantle using body wave travel time data).

On the global scale, as in source studies, two different approaches emerged, one based on dispersion measurements in the frequency domain, the other based on time-domain waveform inversions. Dispersion measurements in the frequency domain have been focused primarily on the fundamental mode, and thus limited in resolution beyond depths of 350–400 km. This approach has led to several generations of collections of global phase velocity maps at discrete frequencies. These maps can then be inverted jointly, in a second step, to infer 3D *S*-velocity structure of the upper mantle. This approach was

pioneered by Nakanishi and Anderson (1983) and Nataf *et al.* (1986), and is now well established, with different research groups introducing various improvements in the measurement technique leading to increasingly high-resolution maps (e.g., Trampert and Woodhouse, 1995; Laske and Masters, 1996; Zhang and Lay, 1996; Ekström *et al.*, 1997). Trampert and Woodhouse (1995) designed an automatic method to measure phase and amplitude of surface waves in the period range 40–150 sec and invert the resulting dataset to obtain global phase velocity maps expanded in spherical harmonics up to degree 40. On the other hand, Ekström *et al.* (1997) used phase-matched filters to isolate the fundamental mode and make global dispersion measurements in the period range 35–150 sec and obtain models of phase velocity also up to degree 40 in spherical harmonics. In these studies, lateral variations of structure seem to be well resolved down to wavelengths of ~1000–2000 km. At the long-period end the period range is limited by the difficulty of separating consecutive wave trains, and at the short period end by the increased complexity of surface wave propagation in the strongly heterogeneous crust and uppermost mantle, resulting in lateral refractions and multipathing. The latter are not taken into account by the simple high-frequency, great circle propagation assumptions underlying the interpretation procedures.

Still in the frequency domain, but aiming at exploiting both the real and imaginary parts of the spectrum, Dziewonski and Steim (1982) developed a method to retrieve both phase velocity and attenuation averaged over complete great circle paths. These authors considered the frequency-dependent transfer function $T(\omega)$ between two consecutive fundamental mode Rayleigh wave trains traveling in the same direction along the great circle linking the epicenter and the station (say, R_n and R_{n+2}) and related it to the average dispersion and attenuation over the great circle path:

$$T(\omega) = \frac{R_{n+2}}{R_n} \quad (17)$$

$$T(\omega) = \exp \left\{ -\pi a \left[i \left(2k(\omega) - \frac{1}{a} \right) + \frac{\omega q(\omega)}{2U(\omega)} \right] \right\}$$

where $k(\omega) = \omega/C$ is the real wavenumber, $U(\omega)$ is group velocity, $q(\omega)$ is the inverse of the quality factor, and the extra term $i\pi$ accounts for polar passages. The transfer function $T(\omega)$ is linearized and compared to that predicted by a reference model, to retrieve perturbations in phase velocity C and attenuation q along the great circle.

In order to proceed to a time-domain waveform inversion, synthetic seismograms needed to be computed in a reference model and perturbed. First-order perturbation theory had been developed in the 1970s, culminating in the work of Woodhouse and Dahlen (1978) and Woodhouse (1980b). Without going into detail beyond the scope of this chapter, we will briefly point out the key steps that led to the formalism routinely used today. An asymptotic expression relating the

observed frequency shift $\delta\hat{\omega}_k$ of a normal mode k observed on a given source station path to the underlying average elastic structure over the corresponding great circle path was derived by Jordan (1978) and Dahlen (1979):

$$\delta\hat{\omega} = \frac{1}{2\pi} \int_0^{2\pi} \delta\omega_k(s) ds \quad (18)$$

where the local frequency shift $\delta\omega_k(s)$ represents an integral over depth of the difference between the local elastic structure and the reference Earth model at point s along the source–station great circle, weighted by the depth sensitivity kernels of mode k (e.g., Woodhouse and Gernius, 1982). The local frequency shift can be related to the phase velocity perturbation using Jeans's formula. A perturbed synthetic seismogram could then be formed as a sum over normal modes:

$$u(\Delta, t) = \text{Re} \left[\sum_k A_0^k(\Delta) \exp(i(\omega_k + \delta\hat{\omega}_k) \exp(-(\alpha_k + \delta\hat{\alpha}_k)t) \right] \quad (19)$$

where Δ is epicentral distance in radians, and the amplitude term A_0^k , frequency ω_k , and attenuation α_k are computed in the reference spherically symmetric Earth model. $\delta\hat{\omega}_k$ and $\delta\hat{\alpha}_k$ are the real and imaginary parts, respectively, of the average frequency shift along the complete great circle path. However, this expression only reflects the effect of heterogeneity that is symmetric with respect to the center of the Earth, in agreement with the fact that, to zeroth order in the asymptotic approximation, normal modes are only sensitive to that part of lateral heterogeneity (e.g., Woodhouse, 1983).

Relating observed waveforms of a single (say, the first arriving) surface wave to a synthetic normal mode seismogram presented a challenge. From the practical point of view, this stumbling block was removed by Woodhouse and Dziewonski (1984), who introduced a “distance shift” that depended on the structure of the minor arc in the computation of the seismogram in a slightly heterogeneous Earth, as follows:

$$u(\Delta, t) = \text{Re} \left[\sum_k A_0^k(\Delta + \delta\Delta) \exp(i(\hat{\omega}_k + \delta\hat{\omega}_k) \exp(-\alpha_k t) \right] \quad (20)$$

where the summation is over all modes k , and

$$\delta\Delta = \frac{\omega_k a}{(1 + 1/2)U} (\delta\tilde{\omega} - \delta\hat{\omega}) \quad (21)$$

Here U is the group velocity of the mode k , a is the radius of the Earth, and $\delta\tilde{\omega}$ is the minor arc average of the local frequency shift $\delta\omega$, defined as

$$\delta\tilde{\omega} = \frac{1}{\Delta} \int_0^\Delta \delta\omega(s) ds \quad (22)$$

Theoretical proofs of Eqs. (20) and (21) were later given independently by Romanowicz (1987), Park (1987), and

Mochizuki (1986a,b), in the framework of zeroth-order asymptotic coupling theory (Woodhouse, 1983; Tanimoto, 1984). The minor arc average $\delta\tilde{\omega}$ arises as a consequence of coupling of neighboring modes along a single dispersion branch, due to lateral heterogeneity, in contrast to the great circle average, which is obtained through coupling within isolated mode multiplets (Jordan, 1978; Woodhouse, 1983; Romanowicz and Roullet, 1986).

The frequency-domain approach involves a two-step procedure: First, determine phase velocity maps of a single surface wave mode branch at individual frequencies; second, invert the dispersion curves obtained at every point on the globe to obtain the laterally varying depth distribution of shear velocities (since surface waves are primarily sensitive to shear velocity). On the other hand, the waveform approach is a single-step approach that obtains the 3D structure directly from the seismograms. Moreover, it can also be used for multimode waveforms, the approach favored by Woodhouse and Dziewonski (1984) and later extended, in combination with body wave travel time measurements, to whole-mantle tomography (e.g., Su *et al.*, 1994).

Whatever the approach, a significant issue regarding the inversion of fundamental mode surface waves is that of crustal corrections. Indeed, surface waves are sensitive to shallow crustal structure even at long periods (e.g., Dziewonski, 1971). Most studies perform crustal corrections in the framework of linear perturbation theory. However, Montagner and Jobert (1988) showed that the effect of strongly varying crustal structure is nonlinear and proposed a more accurate correction procedure based on a tectonic regionalization. The nonlinear part comes primarily from very large lateral variations in depth to Moho and other crustal discontinuities (for example, depth to Moho can vary by a factor of 4 between oceans and continents). The crustal contribution is computed in two steps. First, $i = 1 - n$ regional reference models are considered, and phase velocities as well as partial derivatives with respect to elastic parameters and discontinuity depths are computed for each of these models. In a second step, linear corrections are applied for each point along the source–station path, taking into account perturbations of the actual crustal elastic parameters and discontinuity depths with respect to the local tectonic model. The contribution $\Delta\Phi$ to the observed phase, due to crustal structure, is thus of the form:

$$\frac{\Delta\Phi}{\omega} = \sum_i \left[\int_S^R ds(M) \frac{\delta_i(M)}{C_i} - \int_S^R ds(M) \frac{\delta_i(M)}{C_i^2} \times \left(\sum_r \frac{\partial C}{\partial p_{ir}} \delta p_{ir} + \sum_k \frac{\partial C}{\partial h_{ik}} \delta h_{ik} \right) \right] \quad (23)$$

where $\delta_i(M)$ is 1 if point M belongs to a tectonic region i , and 0 otherwise; C_i is the phase velocity in crustal model i ; h_{ik} is the depth of the k th discontinuity of the tectonic model i ; and δh_{ik}

is the perturbation in that depth at point M . Also, p_{ir} is the r th elastic parameter in tectonic model i , and δp_{ik} is the perturbation in that parameter at point M . Montagner and Jobert (1988) give a slightly different expression for the crustal contribution, arguing that only the lateral variations in discontinuity depths need to be treated in a nonlinear fashion.

Developing accurate crustal models (e.g., Mooney *et al.*, 1998) remains a challenge for large-scale surface wave inversions for structure, as does the accurate treatment of crustal effects.

4.2 Higher-Mode Surface Wave Inversion

While well separated in the time domain from other mode branches and therefore well suited for single mode analysis techniques, fundamental mode surface waves have several shortcomings: at intermediate periods (say, 20–150 sec) their sensitivity to structure below about 200 km is poor, whereas longer-period mantle waves, which reach down to the top of the transition zone, have poor spatial resolution. In any case, resolving structure in the upper mantle transition zone, which is also poorly sampled by body waves, requires the analysis of higher-mode surface waves, whose sensitivity is larger at these depths (Fig. 6). They are also a powerful tool for investigating structures where low velocity zones may be present (e.g., Kovach and Anderson, 1964).

In some specific frequency windows, and for some specific source excitations, it has been possible to isolate and measure the dispersion of the first higher Rayleigh wave modes, either at very short period, where they are well separated on the seismogram (e.g., Crampin, 1964), or with the help of time-variable filtering at periods between 100 and 200 sec (e.g., Roult and Romanowicz, 1984). In general, however, higher-mode surface waves overlap in the time–frequency domain, and single mode dispersion methods therefore cannot be applied. For example, in the period range 80–150 sec, Rayleigh modes 3, 4, and 5 are well excited by intermediate-depth earthquakes, and are observed on seismograms as single energetic wavepackets, labeled “X-phase” by Jobert *et al.* (1977).

In the 1970s, in order to isolate higher modes of surface waves, similar array methods were developed independently by Nolet (1975) and Cara (1973b, 1978) and applied in the period range 20 to 100 sec to paths across Eurasia and the Pacific Ocean, respectively.

These methods require a linear regional array of stations approximately aligned with the epicenter (and not in a nodal direction) to separate modes in the (ω, k) domain, where k is wavenumber. After correction for the instrument response, an array stack is formed (e.g., Nolet, 1975):

$$S(\hat{k}, \omega) = \left| \sum_n F_n(\omega) \exp(i\Phi_n) H_n(\hat{k}, \omega) \right|^2 \quad (24)$$

FIGURE 6 Depth profiles of partial derivatives of Rayleigh wave fundamental and first three higher modes with respect to S velocity at a period of ~ 100 sec, computed in the PREM model (Dziewonski and Anderson, 1981). At this period, the fundamental mode sensitivity peaks around 150 km depth and is negligible below 300 km depth. On the other hand, higher modes have significant sensitivity throughout the transition zone, and even, for modes 2 and 3, at the top of the lower mantle. (Courtesy of Yuancheng Gung.)

where the “array response” is

$$|H_n(\hat{k}, \omega)|^2 = \left| \frac{1}{N} \sum_j \exp[i(k_n(\omega) - \hat{k})\Delta_j] \right|^2 \quad (25)$$

and $F_n(\omega)$, $\Phi_n(\omega)$, and $k_n(\omega)$ are, respectively, the amplitude spectrum, initial phase, and wavenumber of mode n , Δ_j is the epicentral distance to station j , and the spectrum of the multi-mode signal at station j is

$$W_j(\omega) = \sum_n F_n(\omega) \exp[ik_n(\omega)\Delta_j + i\Phi_n(\omega)] \quad (26)$$

The array-response has a peak at $\hat{k} = k_n$. These peaks are measured from plots of contours of the function $S(\hat{k}, \omega)$ in the $(\omega, \hat{k})$ plane, from which dispersion curves $k_n(\omega)$ are then derived (Fig. 7).

This method is nevertheless limited in its application to a few regions of the world with relatively dense, linear arrays. The condition of alignment of the array in a narrow azimuthal range was later relaxed by Okal and Jo (1985, 1987), by correcting for the azimuthal variations of the initial phase $\Phi_n(\omega)$. This approach still suffered from lack of accuracy in the reading of the maxima in the $S(\hat{k}, \omega)$ plots, in particular due to the presence of large side-lobes.

FIGURE 7 Example of UC diagram for the determination of dispersion of Rayleigh wave higher modes. This diagram was obtained from records of WWSSN stations in North America, at a period of 35 sec, for an event in Fiji-Tonga, which occurred on 13 Oct. 1969 at a depth of 246 km. The numbers indicate amplitude levels in percent of maximum. The maxima correspond to modes 1, 2, and 3, traveling with similar group velocities, but well separated in phase velocity. (Reproduced with permission from Cara, 1978.)

In the meantime, following a cross-correlation technique first proposed by Dziewonski *et al.* (1972), a waveform-based method involving the comparison of single record observed and synthetic seismograms was developed by Lerner-Lam and Jordan (1983) and later improved by Cara and L  v  que (1987) and L  v  que *et al.* (1991). In this approach, branch cross-correlation functions (bccf's) are formed between a particular single-mode synthetic and the observed seismogram, as follows. The observed seismogram $s(t)$ is written as the sum over overtone branches $u_n(t)$,

$$s(t) = \sum_n u_n(t) \quad (27)$$

and a synthetic seismogram $\tilde{s}(t)$ is computed for a reference spherically symmetric model suitable as a starting model for the average structure along the source-station path considered:

$$\tilde{s}(t) = \sum_n \tilde{u}_n(t) \quad (28)$$

The matched filter is the synthetic seismogram $\tilde{u}_m(t)$ for a particular mode branch m , so that the objective function to be

minimized is formed as

$$\mathcal{O}_n(\tau) = (s(t) - \tilde{s}(t)) * \tilde{u}_m(t) \quad (29)$$

The objective function should be peaked near $\tau = 0$, and the displacement of the peak from $\tau = 0$ is a function of the difference between the observed and the computed dispersion.

Partial derivatives with respect to model parameters can be formed to then invert for elastic model perturbations and obtain an average structure along the specific source-station path. Cara and L  v  que (1987) added a bandpass filter to further improve the resolution, and L  v  que *et al.* (1991) added a procedure to invert the envelope and phase of the filtered cross-correlograms. Indeed, this formalism lends itself also to the derivation of secondary observables such as group or phase velocities, which have a more linear dependence on the elastic structure, an approach discussed by Cara and L  v  que (1987) and also further developed by Gee and Jordan (1992). The main drawback of this cross-correlation methodology is the contamination of the single mode objective function by interference from other modes.

Other waveform inversion approaches have been developed that do not try to separate individual higher modes. Nolet (1990) introduced the “partitioned waveform inversion” approach in which inversion for elastic structure proceeds in two steps. Path integral parameters are defined and retrieved by nonlinear waveform fitting and, in a second step, inverted linearly for elastic structure. The main goal of this approach is to reduce the number of parameters to be fit in the nonlinear part of the inversion, and thereby to simplify the computations and increase their robustness. This method has subsequently been applied by Zielhuis and Nolet (1994) to retrieve upper mantle structure under central Europe, by van der Lee and Nolet (1997) in North America, and by Zielhuis and van der Hilst (1996) in Australia.

Alternatively, following the waveform modeling approach of Woodhouse and Dziewonski (1984), Li and Romanowicz (1995, 1996) introduce a global waveform modeling approach, based on a theoretical normal mode formalism that includes coupling across different mode branches (Li and Tanimoto, 1993). This formalism is particularly appropriate for body waves, in that it involves the computation of broadband sensitivity functions centered around the ray path, a more correct approach than the standard surface wave path average approximation, which averages kernels laterally between the source and the receiver. However, for higher-mode surface wave trains with sensitivity to the top of the lower mantle, across-branch mode coupling also starts to matter if increased resolution of structure is to be attained (e.g., Mégnin and Romanowicz, 1998). A similar mode-coupling formalism, using a propagating wave approach in the frequency domain, has been derived by Marquering and Snieder (1995) and Zhao and Jordan (1998).

Efforts to extract single mode observables using a waveform approach continued in the 1990s. Stutzmann and Montagner (1993, 1994) directly compare observed and synthetic waveforms of multimode wavepackets for paths between several earthquakes approximately in the same location, but at different depths, and for a given station. They set up an iterative, nonlinear inversion, in which they assume that the only unknowns are perturbations of the phase velocities of the fundamental mode and first few higher modes (in general three) along each path. They thus retrieve path-dependent dispersion properties, which, in a second step, they combine in a global inversion for structure. The drawback of this method is the constraint on path selection imposed by the requirement of finding several well-recorded neighboring earthquakes of different depths, which limits the number of paths that can be processed around the Earth, and therefore the resolution of the model.

Recently, van Heijst and Woodhouse (1997, 1999) proposed a “mode-branch stripping” method based on a bccf approach combined with a frequency-stepping procedure. These authors proceed iteratively to extract phase velocity and amplitude information, as a function of frequency, for the well-excited

modes contained in a higher-mode wavepacket. They start at low frequency and proceed to higher frequencies, taking advantage of the smoothness of dispersion as a function of frequency, and thus are able to avoid the indeterminate 2π phase shifts that can be a problem at higher frequencies. By computing synthetics, they also determine the respective strengths of the different mode branches, and start the procedure by fitting the strongest mode branch. The improved synthetics for this mode branch are then subtracted from the data and the procedure is repeated for the next strongest mode with data and synthetics “stripped” of the already fitted preceding mode. At each step, the objective function to be minimized for mode q is then

$$\mathcal{O}_q(\tau) = (s^{-p_1 p_2 \dots}(t) - \tilde{s}^{-p_1 p_2 \dots}) * \tilde{u}_q(m) \quad (30)$$

where $s^{-p_1 p_2 \dots}(t)$ and $\tilde{s}^{-p_1 p_2 \dots}$ are the observed and synthetic seismograms, respectively, stripped of the modes $p_1, p_2, \dots$ that have already been fit.

van Heijst and Woodhouse (1997) argue that this approach not only provides better resolution for a given path than the original bccf approach, but, by allowing the determination of single mode dispersion and amplitude with many fewer restrictions on the paths than the method of Stutzmann and Montagner (1993), it also leads to better sampling of the globe and, not being limited to theoretical assumptions on great circle path propagation, leaves open the possibility of extracting information on off-path propagation.

4.3 Upper Mantle Anisotropy from Fundamental Mode Surface Waves

The incompatibility of dispersion curves measured for Love and Rayleigh waves has provided some of the earliest evidence for anisotropy in the crust and upper mantle (e.g., Anderson, 1961; Aki and Kaminuma, 1963; McEvilly, 1964). Its widespread character was confirmed in the 1970s and 1980s, mainly for fundamental modes, and in the oceans (e.g., Forsyth, 1975; Schlue and Knopoff, 1977; Mitchell and Yu, 1980; Montagner, 1985), but also for higher modes (Levêque and Cara, 1983). This discrepancy can be explained by introducing a transversely isotropic medium with vertical symmetry axis, and it is in this framework that the widely used Preliminary Reference Earth Model (PREM) has been constructed (Dziewonski and Anderson, 1981). Studies of the Love/Rayleigh discrepancy have been extended to the global scale and at long periods (100–250 sec) by Nataf *et al.* (1984), who first mapped the global lateral variations of transverse isotropy as a function of depth, expanded in spherical harmonics up to degree 6.

Recently, Ekström and Dziewonski (1998) used global Love and Rayleigh wave dispersion measurements in the period range 35–300 sec, complemented by long period waveform and travel time data, to invert separately for V_{SH} and V_{SV} in

the upper mantle, and thus obtain a measure of the global distribution of transverse isotropy. Their model (“S20”), which is expanded laterally in spherical harmonics up to degree 20, confirms the widespread presence of this type of anisotropy in the upper mantle, and particularly singles out a strong anomaly in the central Pacific Ocean.

In addition, surface wave dispersion has also been shown to vary with azimuth, another indication of anisotropy (e.g., Forsyth, 1975; Suetsugu and Nakanishi, 1987). The global azimuthal variations of Rayleigh and Love wave dispersion at long periods (100–250 sec) were first mapped by Tanimoto and Anderson (1984, 1985), who showed that the fast direction appears to correlate with flow directions in the mantle.

Surface waves thus show two manifestations of anisotropy: (1) variations of phase and group velocities with azimuth (azimuthal anisotropy), and (2) inconsistent dispersion curves for azimuthally averaged Love and Rayleigh waves (transverse isotropy).

The theoretical expressions for the propagation of surface waves in an anisotropic plane layered medium was studied by Crampin (1970) and Smith and Dahlen (1973). The latter provided expressions for the azimuthal dependence of Love and Rayleigh waves in a slightly anisotropic medium. This formalism was extended to the case of a spherical Earth in a normal mode and spherical harmonics framework by Tanimoto (1986) and Mochizuki (1986b). Romanowicz and Snieder (1988) developed an equivalent formalism that does not require a spherical harmonics expansion and thus is applicable to regional studies, and Park (1997) generalized this to include source terms and compute complete synthetic seismograms in the Born approximation.

Here, we only present the basic asymptotic expressions that relate dispersion to anisotropic elastic structure. To first order in anisotropy, and at frequency ω , the azimuthal variation of phase velocity (Love or Rayleigh wave) is of the form:

$$C(\omega, \theta) = A_1(\omega) + A_2(\omega) \cos 2\theta + A_3(\omega) \sin 2\theta + A_4(\omega) \cos 4\theta + A_5(\omega) \sin 4\theta \quad (31)$$

where θ is the azimuth of the wavenumber vector defined clockwise from north.

Montagner and Nataf (1986) provided expressions for the coefficients $A_i(\omega)$, which are depth integral functions, in terms of the following combinations of standard cartesian elastic coefficients C_{ij} , for both Love and Rayleigh waves:

Constant term (A_1):

$$\begin{aligned} A &= \rho V_{PH}^2 = \frac{3}{8}(C_{11} + C_{22}) + \frac{1}{4}C_{12} + \frac{1}{2}C_{66} \\ C &= \rho V_{PV}^2 = C_{33} \\ F &= \frac{1}{2}(C_{13} + C_{23}) \\ L &= \rho V_{SV}^2 = \frac{1}{2}(C_{44} + C_{55}) \\ N &= \rho V_{SH}^2 = \frac{1}{8}(C_{11} + C_{22} - \frac{1}{4}C_{12} + \frac{1}{2}C_{66}) \end{aligned} \quad (32)$$

2 θ azimuthal term:

$$\begin{array}{ll} (A_2) & (A_3) \\ \cos 2\theta & \sin 2\theta \\ B_c = \frac{1}{2}(C_{11} - C_{22}) & B_s = C_{16} + C_{26} \\ G_c = \frac{1}{2}(C_{55} - C_{44}) & G_s = C_{54} \\ H_c = \frac{1}{2}(C_{13} - C_{23}) & H_s = C_{36} \end{array} \quad (33)$$

4 θ azimuthal term:

$$\begin{array}{ll} (A_4) & (A_5) \\ \cos 4\theta & \sin 4\theta \\ E_c = \frac{1}{8}(C_{11} + C_{22}) - \frac{1}{4}C_{12} - \frac{1}{2}C_{66} & E_s = \frac{1}{2}(C_{16} - C_{26}) \end{array} \quad (34)$$

The term A_1 , independent of azimuth, involves only the five independent combinations of elastic coefficients needed to describe a transversely isotropic medium with vertical symmetry axis, labeled A, C, F, L, N (Love, 1927; Takeuchi and Saito, 1972). Montagner and Nataf (1986) showed that the partial derivatives of all the other terms only require the computation of partial derivatives with respect to the five parameters of a reference transversely isotropic Earth, thus providing the means to invert the azimuthal variations of surface wave phase velocities. They also estimated the different terms for realistic upper mantle models and showed that for Love waves, the N kernel is much larger than L and that the 4 θ term is dominant, making it difficult to use Love waves to constrain azimuthal anisotropy on the global scale, whereas for Rayleigh waves the 2 θ term prevails. Finally, because Rayleigh waves are sensitive both to shallow crustal and deeper mantle anisotropy, it is important to use a wide frequency range to resolve the depth dependence of anisotropy using surface waves.

Montagner and Nataf (1988) showed how this formalism could be used for the inversion of surface wave dispersion data including the azimuthal terms, under the assumption that the material possesses a symmetry axis (orthotropic medium). In this case the 3D model can be described using seven parameters (plus density): the five parameters A, C, F, L, N describing transverse isotropy, and two angles describing the orientation in space of the axis of symmetry. These authors used the inversion algorithm of Tarantola and Valette (1982) in its continuous form, as adapted to surface waves by Montagner (1986) with the introduction of an appropriate spatial correlation function, providing the description of the model and its error distribution on a grid of points (rather than a global basis function expansion), suitable for regional studies. This methodology, called “vectorial tomography,” was first applied by Montagner and Jobert (1988) to retrieve lateral heterogeneity and anisotropy, described at each point by an amplitude scalar, and a direction vector (under the hypothesis of orthotropy), to the study of the Indian Ocean, and the results were interpreted in terms of flow in the mantle.

This procedure involves two steps: (1) determining maps of azimuthal variations of anisotropy at individual frequencies, and (2) inverting the retrieved coefficients locally for heterogeneity and anisotropy variations with depth. A similar approach was subsequently applied to many other regions (e.g., Mocquet *et al.*, 1989; Roult *et al.*, 1994; Griot *et al.*, 1998; Pillet *et al.*, 1999), and extended to the global study of heterogeneity and anisotropy in the upper mantle by Montagner and Tanimoto (1990, 1991). In this latter case, an approximation was introduced for the calculation of the data covariance matrix in the Tarantola and Valette (1982) framework, to make the computations manageable for a global dataset. While some questions linger about trade-offs between lateral heterogeneity and anisotropy in this type of inversion, Montagner and collaborators have shown that they can explain their datasets with fewer parameters when azimuthal anisotropy is considered than when it is ignored.

In order to circumvent the trade-off between lateral heterogeneity and azimuthal anisotropy, Park and Yu (1992, 1993) have looked for other diagnostic effects of anisotropy in long-period surface waves, such as waveform anomalies caused by Rayleigh–Love coupling, which generates “quasi-Love” waves on vertical components and “quasi-Rayleigh” waves on transverse components. Yu and Park (1994) have documented such observations, best seen in nodal directions of strike-slip sources, in the Pacific Ocean and inferred small scale variations in anisotropy related to tectonic features.

4.4 Effects of Scattering and Non-Great Circle Path Propagation

Until now, most regional and global models using surface waves have been derived using the standard “path-average” approximation, which is a high-frequency asymptotic approximation in which the propagation is assumed to be confined to the great circle path between the source and the receiver. This is valid only if the wavelength of lateral variations of structure is long with respect to that of the surface waves considered.

In fact, over the years, there have been many observations indicating that lateral heterogeneity is strong enough to cause departures from this simple hypothesis, as evidenced, for example, at short periods, where 20 sec surface waves sensitive to shallow crustal structure consistently show multipathing (e.g., Capon, 1970; Bungum and Capon, 1974; Fig. 8), or at long periods ($T > 100$ sec), where amplitude anomalies have been widely documented, with, for example, later-arriving trains showing larger amplitudes than the ones preceding them (Fig. 9), which cannot be explained by lateral variations of anelasticity (e.g., Lay and Kanamori, 1985; Roult *et al.*, 1986; Park, 1987).

Several approaches have been developed to try to explain these effects and exploit them to obtain better constraints on lateral variations of structure. The principal ones are cast in the

FIGURE 8 Vertical component records at BDSN stations YBH, ORV, and CMB for the 12/06/2000 earthquake in Turkmenia (M_b 6.7; M_w 7.0; depth 33 km). The records have been bandpass filtered between 0.001 and 0.03 Hz. These records show clear evidence of multipathing of 20–30 sec surface waves. The corresponding great circle path has an azimuth coming from the north which runs quasi parallel to the major structural boundaries in the crust in northern California (including the coast line). Multipathing is more severe at more southerly stations ORV and CMB, indicating that it does indeed originate on the station side. (Courtesy of Yuancheng Gung.)

framework of three different formalisms, depending on the application: ray theory, scattering theory, and a coupled-mode formalism. Each of these methods lends itself to various degrees and, under specific circumstances, to inversion.

Working in a 2D cartesian framework for the description of surface wave propagation in a smoothly laterally varying medium, Woodhouse (1974) introduced the concept of local modes. These are the surface wave modes corresponding to a laterally homogeneous model, which locally has the depth distribution of the laterally varying model. If the medium is smooth, the local mode branches propagate as independent wave trains, the dispersion and displacement of which are modified according to the evolution of the local modes. However, when the lateral variations are sharp (for example, in the presence of a structural discontinuity such as an ocean–continent boundary), the coupling of the local modes cannot be neglected, and its strength depends on the width of the structural transition zone (Kennett, 1972). Kennett (1984)

FIGURE 9 Examples of amplitude anomalies due to focusing for Earth-circling Rayleigh waves. Top traces are observed waveforms and bottom traces are synthetics computed in the spherically symmetric PREM model (Dziewonski and Anderson, 1981). In the synthetics, the later-arriving trains always have smaller amplitudes than the observed ones. In these examples, the data exhibit larger amplitudes in R_3 than in R_2 . The data have been bandpassed filtered between 90 and 400 sec (event C110696M) and 90 and 300 sec (event C012499A). (Courtesy of Yuancheng Gung.)

derived a formalism for mode-coupling in 2D laterally varying structures using a representation of the displacement field on the modes of a reference, laterally homogeneous structure, which still requires continuity in the lateral variations. The coupled, reference mode approach has been extended to the 3D scattering case and for certain types of structures, in cartesian coordinates, by Bostock (1991, 1992) and Bostock and Kennett (1992).

To overcome the restriction of smooth lateral variations, coupled local modes need to be considered. In this case, the wavefield is expanded in terms of a laterally varying local mode basis. A specific case, that of Love waves in a one-layered laterally varied structure, was studied by Odom (1986), whereas Maupin (1988) generalized the coupled local mode approach to any 2D structure. In this case, no reference laterally homogeneous structure is needed.

While 2D mode coupling can provide exact computations of coupling and conversion, and is appropriate for certain applications such as the study of continental margins, a scattering formalism has been, so far, more easily implemented in the context of inversion for the study of 3D heterogeneity in relatively smooth media.

Several applications of ray theory have been proposed to study the departure of surface wave paths from the conventional great circle approximation. Theoretical calculations were proposed by Woodhouse (1974), Babich *et al.* (1976),

and Hudson (1981). Using a simple transformation from cartesian to spherical coordinates, Jobert and Jobert (1983) traced low-frequency Earth-circling mantle waves in a smoothly varying heterogeneous model using a combination of spherical Earth normal mode theory and a Gaussian beam computation scheme (Červený *et al.*, 1982), and showed significant amplitude and travel time anomalies for a model of heterogeneity with strength of $\sim 5\%$. At the regional, shorter period scale, Tanimoto (1990) showed how to compute the full wavefield of surface waves in a smoothly varying heterogeneous medium using an approximate scalar wave equation, and applied this to illustrate the distortion of surface waves propagating across California. Numerical computations showing the strong effects of lateral heterogeneity on the surface wavefield, in the framework of ray theory, were also performed by Yanovskaya and Roslov (1989). Tromp and Dahlen (1992a,b) developed a JWKB theory for the propagation of monochromatic surface waves in an Earth model with smooth lateral variations. These studies, however, did not result in any inversion procedures.

On the other hand, Yomogida and Aki (1985) used the Gaussian beam approach to compute intermediate period (20–80 sec) fundamental mode surface waveforms. They showed that, in this Born approximation framework, the amplitudes of surface waves depend on the second spatial derivatives of the phase velocity distribution, whereas the ray path depends on the first spatial derivatives and the phase on the phase velocity distribution itself. Based on this approach, they developed an inversion method for amplitude and phase data and applied it to retrieve phase velocity anomalies in the Pacific Ocean (Yomogida and Aki, 1987). The same dependence of phase and amplitude anomaly on the underlying phase velocity structure was derived independently by Woodhouse and Wong (1986) using ray theory based on the formalism of Woodhouse (1974). These authors showed that amplitude anomalies, as observed for long-period mantle waves on multiple Earth-circling paths, can be caused by focusing or defocusing due to lateral heterogeneity. Wong (1989) applied this theory to the retrieval of very long-period global mantle wave phase velocity maps from measured phase and amplitude anomalies. Since they depend on transverse gradients of structure along the propagation path, the amplitude anomalies can help constrain smaller-scale lateral variations of structure. The expression for the phase ($\delta\Phi$), amplitude ($\delta A/A_0$), and polarization (ν) anomalies obtained in this framework, at epicentral distance Δ , are of the forms, respectively:

$$\delta\Phi = \frac{1}{\Delta} \int_0^\Delta \frac{\delta c(\pi/2, \phi)}{c_0} d\phi \quad (35)$$

$$\frac{\delta A}{A_0} = \left(\frac{1}{2 \sin \Delta} \right) \int_0^\Delta \left[\sin(\Delta - \phi) \partial_\theta^2 \left(\frac{\delta c}{c_0} \right) \sin \phi - \partial_\phi \left(\frac{\delta c}{c_0} \right) \cos \phi \right] d\phi \quad (36)$$

$$\nu(\Delta) = -\text{cosec}(\Delta) \int_0^\Delta \sin \phi \partial_\theta \left[\frac{\delta c(\pi/2, \phi)}{c_0} \right] d\phi \quad (37)$$

In these equations, the great circle path under consideration has been rotated to lie along the Equator, along which the angle ϕ is measured ($\phi=0$ at the epicenter and $\phi=\Delta$ at the receiver). ν is related to the azimuth Θ along the great circle path by $\nu=\tan(\Theta)$. The local perturbation in phase velocity at a point along the source receiver path is $\delta c/c_0$. We note that the phase $\delta\Phi$ depends only on the phase velocity along the source station path [Eq. (35)]. On the other hand, the amplitude and polarization depend on first and second derivatives of the phase velocity, that is, on gradients of the phase velocity distribution, which in turn depend on short-wavelength features of that distribution. The expression under the integration sign in Eq. (36) actually corresponds to the transverse gradient in the direction perpendicular to the source station great circle (e.g., Romanowicz, 1987). Thus, amplitude and polarization anomalies potentially provide constraints on shorter-wavelength structure. Romanowicz (1987) showed that these expressions are equivalent, for relatively short propagation times, to those obtained for the perturbation to a low-frequency seismogram using a normal mode formalism, under an asymptotic approximation up to order $(1/l)$ in the development of spherical harmonics Y_l^m . In particular, the normal mode derived expression for the amplitude perturbation is

$$\frac{\delta A}{A} = -\frac{a\Delta}{U} \left(\frac{\tilde{D}}{2(l+1/2)} \right) \quad (38)$$

where U is group velocity and $\tilde{D}$ is the minor-arc average of the second transverse derivative of the local frequency perturbation along the source–station great circle path. These expressions for amplitude anomalies were considered by Romanowicz (1990) and Durek *et al.* (1993) in attempts to separate the effects of focusing and intrinsic attenuation on the global scale.

Laske (1995) and Laske and Masters (1996) used expression (37) for the azimuth anomaly to interpret observed polarization anomalies, measured using a multitaper technique (Park *et al.*, 1987), in terms of lateral variations of phase velocities on the global scale and thus retrieve shorter-scale variations than can be obtained with the same global distribution of observations using phase data alone. Polarization analysis using the same multitaper technique had been proposed previously for the study of lateral heterogeneity by Lerner-Lam and Park (1989) and Paulssen *et al.* (1990).

Expression (35) for phase anomaly is correct to first order in lateral heterogeneity. Pollitz (1994) calculated the second-order contribution to the phase and concluded that it is unimportant for global phase velocity models expanded up to degree 12 but is potentially important for rougher models

(degree of expansion ≥ 16). That study suggested systematic bias in phase velocity maps that do not account for the second-order effect, though the potential magnitude of that bias requires further exploration. This effect arises from structure gradients perpendicular to the great circle path, suggesting that it should be considered jointly with polarization measurements in global phase velocity inversions.

In the framework of scattering theory, the single-scattering Born approximation, developed for surface waves by Snieder (1986) in a flat Earth geometry and Snieder and Nolet (1987) in a spherical Earth geometry, has been the subject of many studies. Born scattering is well suited for inversion since the scattered wavefield depends linearly on structural perturbations. Indeed, following Snieder (1988a), the surface wave displacement field can be decomposed into a “path average” part u_0^{pava} , computed in a classical fashion, and a Born perturbation δu^{born} :

$$u = u_0^{\text{pava}} + \delta u^{\text{born}} \quad (39)$$

where

$$\delta u^{\text{born}} = \iint \sum_{\nu, \sigma} \mathbf{p}^\nu \frac{e^{i(k_\nu a \Delta_2 + \pi/4)}}{(\sin \Delta_2)^{1/2}} S^{\nu\sigma} \frac{e^{i(k_\sigma a \Delta_1 + \pi/4)}}{(\sin \Delta_2)^{1/2}} \times (\mathbf{E}^\sigma : \mathbf{M}) \sin \theta d\theta d\phi \quad (40)$$

where σ, ν are the excited and scattered modes, respectively, $\mathbf{p}^\nu$ is the polarization vector at the receiver, Δ_1 and Δ_2 are the angular distances to the scatterer from the source and the receiver, respectively, and the scattering matrix $S_{\nu, \sigma}$ depends on elastic structural parameters via coupling kernels K :

$$S_{\nu\sigma} = \int_0^a (K_\mu^{\nu\sigma} \delta\mu + K_\rho^{\nu\sigma} \delta\rho + K_\lambda^{\nu\sigma} \delta\lambda) dr \quad (41)$$

where $\delta\mu$, $\delta\rho$, and $\delta\lambda$ are 3D perturbations to the reference laterally homogeneous model described by $\mu(r)$, $\rho(r)$, $\lambda(r)$. For intermediate- and long-period surface waves, perturbations in S velocity β need only be considered, and $S_{\nu\sigma}$ reduces to

$$S_{\nu\sigma} = \int_0^a K_\beta^{\nu\sigma} d\beta \quad (42)$$

If $d\beta$ is expanded using 3D spatial basis functions, this leads to the linear expression

$$\delta u^{\text{born}} = \sum_i \gamma_i a_i \quad (43)$$

where a_i can be evaluated in the reference medium, and γ_i are the expansion coefficients of $d\beta$ in the 3D spatial basis.

Snieder (1988a) showed how to set up a regional tomographic inversion using many fundamental surface waveforms. This method has been applied to the area of Europe and the Mediterranean by Snieder (1988b) and to North America by Alsina *et al.* (1996), and has been extended to the case of

multimode wave trains by Meier *et al.* (1997). In the latter two cases, the partitioned waveform method of Nolet (1990) has been used in conjunction with Born scattering, to minimize the computational effort involved.

Snieder and Romanowicz (1988) generalized this scattering formalism in the case of spherical earth geometry, and in a normal mode context, by applying an operator formalism as introduced by Romanowicz and Roullet (1986) and Romanowicz (1987), avoiding expansion in spherical harmonics of the 3D Earth model, as previously employed (Woodhouse and Girnius, 1982), and thus making it applicable to the case of any single scatterer (and not only to smooth heterogeneity). In this formalism, the addition theorem of spherical harmonics is used:

$$\sum_m Y_l^{m*}(\theta_s, \phi_s) Y_l^m(\theta, \phi) = \gamma_l Y_l^0(\lambda) \sum_m Y_l^{m*}(\theta, \phi) Y_l^m(\theta_r, \phi_r) = \gamma_l Y_l^0(\beta) \quad (44)$$

where l is the angular order of a normal mode k , (θ_s, ϕ_s) , (θ_r, ϕ_r) and (θ, ϕ) are the coordinates of the epicenter, the receiver, and the scattering point, respectively (Fig. 10), and $\gamma_l = (2l + 1/4\pi)^{1/2}$. Angular distances λ and β are defined in Figure 10. The interaction coefficient $Z_{K,K'}^{m,m'}$ between modes K, K' and their singlets m, m' can then be written simply as

$$Z_{K,K'}^{m,m'} = \sum_{i=0}^2 \iint Op_i(X_l^0(\lambda)) \delta\omega_{KK'}^i(\theta, \phi) Op_i(X_l^0(\beta)) d\Omega \quad (45)$$

where the operators Op_i are linear combinations of differential operators acting on the coordinates (θ, ϕ) of the running point,

FIGURE 10 Geometry for single scattering corresponding to Eq. (45). S and R are the locations of the epicenter and the receiver, respectively. Q is a generic point on the surface of the sphere, and P is the pole of the source receiver great circle γ . (Reproduced with permission from Romanowicz, 1987.)

and incorporate source and receiver effects, computed in the reference spherically symmetric model. The integral is over the unit sphere, and $\delta\omega_{KK'}^i$ are local frequency perturbations, describing depth-integrated effects of perturbations in the elastic model. To zeroth order in an asymptotic expansion in orders of $1/l$, the summation over i reduces to only one term ($i=0$). Expression (45) has the same form as Eq. (40) and they are equivalent in the surface wave, high-frequency limit (Snieder and Romanowicz, 1988). Romanowicz and Snieder (1988) extended the same formalism to the case of a general anisotropic perturbation.

The Born approach is flexible as it is applicable to general 3D structures. However, it is a poor approximation in the case of strong heterogeneity, or when the region of scattering is large, in which case multiple scattering can play an important role.

On the other hand, Friederich *et al.* (1993) proposed an enhanced scattering theory for surface waves in a cartesian geometry, in which multiple forward scattering and single backward scattering are included. They use a potential formalism that can be summarized through the consideration of a scattering kernel K_p^{nm} that includes all the details of the regional scattering problem relevant to two modes n and m , depending only on the structural parameters. The surface wave displacement u for a mode m is decomposed as

$$u_m(x, y, z) = U_m(z) \Phi^m(x, y) \quad (46)$$

where Φ^m is the displacement potential and U is a vertical eigenfunction

$$\Phi_s^{nm}(x, y) = \iint dx' dy' K_p^{nm}(x, y|x', y') \Phi^m(x', y') \quad (47)$$

where (x, y) , (x', y') are the coordinates of the observation point and the scattering point respectively, Φ^m is the displacement potential of mode m and Φ^{nm} is the scattered potential of mode n generated by mode m . The computation is simplified by discretizing the model into cells and assuming a piecewise plane wave approximation in each cell. When Φ^m is the potential corresponding to a reference 1D model of mode m , this is equivalent to single scattering theory. Friederich *et al.* (1993) use the reference potential for the row of cells closest to the source, compute the scattered potential $\sum \Phi_s^{nm}$ at all other rows, add the scattered wavefield and use this as starting potential to compute the scattered wavefield in the next row, and so on. They show that the computation thus includes all multiply forward scattered waves, but is incomplete for the backscattered field. This is not a problem in most cases, however, except when sharp, reflecting discontinuities are present. Subsequently, Friederich (1999) extended this approach to the case of spherical geometry and normal mode summation in a global Earth framework, using the operator formalism for the mode coupling terms of Romanowicz (1987). To limit the

amount of computation, they compute only the seismic displacement wavefield between the S wave and the end of the first-arriving surface wave, at epicentral distances shorter than 50° .

Wielandt (1993) showed that the measured (or dynamic) phase velocity of teleseismic surface waves in a regional context is different from the structural phase velocity in the region considered. The former depends strongly on the geometry of the incoming wavefield, which can be distorted by structure along the propagation path outside of the area of study. Based on the work of Friederich *et al.* (1993), Friederich and Wielandt (1995) proposed a method to invert jointly for incoming wavefields and the heterogeneous phase velocity structure within a study region. In this approach, they include the multiple forward and backward scattering terms. They use a plane wave decomposition of the incoming wavefield and they reduce the nonuniqueness of the joint inversion by applying an “energy criterion,” constraining the energy of the total wavefield averaged over all the events considered to be equal to the mean squared amplitude at the stations, also averaged over all events. This method has been applied to fundamental mode surface waves in southern Germany by Friederich (1998) and in northern California by Pollitz (1999). Notably, Pollitz (1999) showed how to relate the inverted 2D phase velocity maps to 3D structure, taking into account both isotropic [$i = 1$ in Eq. (45)] and nonisotropic scattering interactions. The application of these promising methodologies is still in an early development stage, as they present many computational challenges.

4.5 Surface Wave Attenuation Measurements and Inversion for Upper Mantle Anelastic Structure

Surface wave amplitude measurements can be used to try to retrieve information about the anelastic structure of the crust and upper mantle. In the absence of perturbing effects due to scattering and focusing, the amplitude spectrum of a mono-mode wave train i , usually the fundamental mode, can be written as

$$A_i(\omega) = A_0(\omega) \exp(-\eta_i(\omega)) X_i \quad (48)$$

where X_i is the epicentral distance in kilometers and $A_0(\omega)$ represents the amplitude at the source. The attenuation coefficient can be related to Q through (e.g., Aki and Richards, 1980)

$$\eta(\omega) = \frac{\omega}{2C(\omega)Q(\omega)} \quad (49)$$

where C is phase velocity. Surface wave measurements provide the primary constraints on attenuation structure (both variations with depth and lateral variations) in the crust and uppermost mantle. To investigate the radial structure in Q over a wider depth range, long-period surface wave or normal mode

attenuation measurements can be used. Both the radial and the lateral structures in Q are, however, to this day, less well constrained than elastic structure, due to a large extent to the contamination of amplitude data by scattering and focusing effects due to wave propagation in a heterogeneous elastic Earth, as described in the previous section. There still exists an apparent discrepancy (on the order of 15%, Fig. 11) between the measurements of fundamental mode Q obtained using a standing wave approach (e.g., Masters and Gilbert, 1983; Smith and Masters, 1989; Widmer *et al.*, 1991) and those using a propagating wave approach (Dziewonski and Steim, 1982; Romanowicz, 1990, 1995; Durek *et al.*, 1993; Durek and Ekström, 1996). This was investigated by Durek and Ekström (1997), who proposed that the discrepancy could be due to measurement techniques, with the presence of noise leading to an overestimation of Q from normal modes, which require the computation of spectra over long time-series (typically 24 hours). On the other hand, Masters and Laske (1997) have questioned the accuracy of surface wave measurements of Q at very long periods, in particular due to the difficulty of selecting appropriate time windows to isolate the fundamental

FIGURE 11 Fits of various mantle Q_μ model predictions to spheroidal mode data (Sailor and Dziewonski, 1978; Widmer *et al.*, 1991; Resovsky and Ritzwoller, 1998) and Rayleigh wave data (Dziewonski and Stein, 1982; Durek *et al.*, 1993; Romanowicz, 1995; Masters and Laske, 1997), illustrating the discrepancy between measurements obtained using standing wave and propagating wave approaches, respectively. Models QL6 and QM1 were constructed by Durek and Ekström (1996) and Widmer *et al.* (1991) respectively. (Reproduced with permission from Romanowicz and Durek, 2000.)

mode, in the presence of overlapping wave trains. This issue remains to be resolved.

Regional studies of amplitudes of fundamental mode surface waves in the period range 5–100 sec (Anderson *et al.*, 1965; Mitchell, 1975; Canas and Mitchell, 1978, 1981) and of *Lg* waves (Xie and Mitchell, 1990a,b) have long established the existence of large variations of Q in the crust and uppermost mantle, correlated with tectonic provinces and in particular with the age of the oceans, and with time elapsed since the latest tectonic activity on continents. A recent review can be found in Mitchell (1995). At longer periods, large lateral variations also exist (e.g., Nakanishi, 1978; Dziewonski and Steim, 1982). These lateral variations can be an order of magnitude larger than those in elastic velocity.

Progress in using surface wave data to constrain global 3D anelastic structure of the upper mantle has been slow because, as mentioned previously, of the inherent difficulty of measuring attenuation in the presence of focusing and scattering effects that can be as large as or larger than anelastic effects and depend strongly on the short-wavelength details of the elastic structure. Indeed, as discussed previously [Eq. (36)] to first order these effects depend on the transverse gradients of structure along the great circle path linking epicenter and station, which in turn depend on terms of the form $s^2 C_{st}$ where C_{st} are the coefficients of an expansion in spherical harmonics of the elastic model (s and t are the degree and order of the corresponding spherical harmonic Y_s^t). If the elastic structure of the Earth were accurately known to short wavelengths, one could first correct for its effects on the amplitude.

In the meantime, indirect methods have been used to minimize contamination of amplitudes by unwanted elastic effects. Romanowicz (1990) and Durek *et al.* (1993) took advantage of the fact that, in the linear approximation, focusing and anelastic effects could be separated by combining measurements over several consecutive wave trains, since attenuation effects are always additive whereas focusing depends on the direction of propagation. However, the longer the wave path the more the waves are affected by 3D elastic structure, and the harder it is to account for that in a simple approximate fashion. Another source of bias comes from uncertainties in the amplitude at the source. Romanowicz (1994) developed a method that involves computing attenuation coefficients in two ways: (1) using first-arriving trains only; (2) using the first three wave trains. The first measurement involves a source bias, but is less contaminated by elastic effects. On the other hand, in the second measurement, the source effect has been canceled out; however, the attenuation measurement is less accurate, and generally shows large variations with frequency, due to increased elastic effects over the longer paths. Comparison of the two $\eta(\omega)$ curves allows determination of a source correction factor and thus allows one to obtain a relatively accurate attenuation measurement using first- and second-arriving trains only.

Progress in the retrieval of accurate Q information from long-period surface wave data for global modeling is coupled to the development of efficient techniques for the modeling of elastic scattering effects. Recently, Billien *et al.* (2000) have proposed an approach in which phase and amplitude measurements of Rayleigh waves at intermediate periods (40–150 sec) are jointly inverted for elastic and anelastic structure, taking into account the first-order asymptotic focusing term [Eq. (36)]. It is still not clear, however, whether such a first-order, “smooth” approximation is sufficient to rule out biases due to scattering by small-scale heterogeneity.

Another issue is to account for dispersion in velocities due to attenuation, using an absorption band model for the Earth. This has been found to explain the discrepancy between average velocity models obtained using high-frequency body waves and surface waves (Kanamori and Anderson, 1977). However, most of the frequency dependence in surface waves is related to the effects of depth-dependent elastic structure. Surface waves alone cannot resolve the frequency dependence of Q . More detailed recent reviews on global Q structure can be found in Romanowicz (1998) and Romanowicz and Durek (2000).

5. Conclusions

We have reviewed the evolution of the main methodologies based on the inversion of surface wave data over the last several decades. We find that much progress has been made in the last 20 y in the development of surface wave methods to retrieve both source parameters and Earth structure using surface wave data. This progress has built upon fundamental theoretical developments of the 1960s and 1970s, during which the basis for the computation of earthquake source excitation as well as modeling of surface wave dispersion properties in terms of the Earth's structure was established. In the 1980s, surface wave studies have benefited from progress in computer speed and capacity, which, together with the deployment of a new generation of digital, broadband, high dynamic range global and regional seismic networks, has opened the way to large-scale source and structure inversions, with recent efforts to include anisotropic and anelastic contributions, as well as to systematically exploit information contained in overtones.

Most inversions, so far, have been performed under the assumption that the effects of propagation in the laterally heterogeneous Earth can be accounted for using the simple great circle path average approximation, which assumes that surface waves are sensitive only to the structure in the vertical plane containing the source and the receiver, and to the laterally averaged structure along this path. Beyond this approximation, there are two particularly important issues. One is the computation of more accurate kernels for propagation in the vertical plane containing the source and the receiver. This is important for waveform inversion that

includes body waveforms, and is relevant, in the context of this review, to the inversion of overtone waveforms sensitive to the mantle transition zone and greater depths. The first step in this direction has been the incorporation of across-branch coupling effects computed asymptotically to zeroth order, both in a normal mode and in a propagating wave framework. This has started to be put into practice in the context of global waveform inversion (Li and Romanowicz, 1996; Mégnin and Romanowicz, 2000), and should help improve the resolution of shorter-wavelength features of tomographic models. The other issue is that of how to account for scattering and focusing effects, which can be viewed as departures of the wave path from the source–receiver great circle. Theoretical progress on how to describe these effects accurately has been steady, evolving from the consideration of single scattering to the more complex question of multiple scattering. Transition into practice (i.e., into large-scale inversions of real data) still presents many computational challenges. It is, however, a necessary step if the ever-increasing broadband data collection assembled in the last quarter of the 20th century is to be fully exploited to gain improved resolution at shorter wavelengths.

Acknowledgments

This paper was written while the author was on sabbatical leave from UC Berkeley, visiting at the Département de Seismologie, Institut de Physique du Globe in Paris, France. The author thanks three reviewers who contributed to improving the quality of this review.

1. Introduction

Earthquake source dynamics provides key elements for the prediction of strong ground motion and for understanding the physics of earthquake initiation, propagation, and healing. Early studies pioneered our understanding of friction and introduced simple models of dynamic earthquake rupture, typically using homogeneous distributions of stress and friction parameters. Classical examples of such models are the mechanical spring-and-box models proposed by Burridge and Knopoff (1967), the rectangular dislocation model proposed by Haskell (1964), and the self-similar circular rupture model introduced by Kostrov (1966). Extensive research then followed to advance our understanding of seismic rupture propagation and stress relaxation. It became clear that the correct mathematical formulation of the problem of propagation and radiation by a seismic rupture was that of a propagating shear crack as proposed by Kostrov (1964, 1966). Very soon it became clear that friction also played a fundamental role in the initiation, the development of rupture, and the healing of faults. The classical Coulombian model of a sudden drop in friction from a static to a dynamic coefficient led to an impasse, with infinite stress singularities and many other physical problems. The reason is that this model lacks an essential length scale needed to define a finite energy release rate near the rupture front.

Better models of friction at low slip rates were studied in the laboratory by Dieterich (1978, 1979) and Ruina (1983), who proposed the model of rate- and state-dependent friction. Slip weakening friction laws were introduced in dynamic rupture modeling by Ida (1972) and Andrews (1976a,b) for plane (2D) ruptures and by Day (1982b) for 3D fault models. These authors showed that slip weakening regularizes the numerical model of the rupture front, distributing stress and slip concentrations over a distance controlled by the length scale in the friction law. Ohnaka and Kuwahara (1990), Ohnaka (1996), and Ohnaka and Shen (1999) concluded that their experiments

could be explained with a simple slip weakening friction law. In fact, for many practical purposes, the rate-and-state and slip weakening friction laws can be reconciled by noting that both models contain a finite length scale that controls the behavior of the rupture front (see Okubo, 1989; Dieterich and Kilgore, 1996). Extensive reviews on rupture dynamics up to 1990 have been published by Kostrov and Das (1989) and Scholz (1989).

Recent studies of rupture processes for selected earthquakes have shed new light on our understanding of earthquake ruptures. These models suggest a complexity of the rupture process that the early models of rupture in a uniformly loaded medium were unable to explain. Although, in the late 1970s, Das and Aki (1977b), Mikumo and Miyatake (1978, 1979), Madariaga (1979), and Andrews (1980, 1981) pointed out the deficiencies of the classical dislocation and crack models, it was not until the late 1980s that good-quality near-field accelerometry became available for some large earthquakes. Simultaneously, new sophisticated and efficient numerical methods, such as boundary integral equations (BIE) and finite differences (FD), provided the tools to study realistic dynamic rupture propagation in a fault subject to a heterogeneous stress field and spatially varying friction.

Heaton (1990) noticed that rupture of large earthquakes was typically characterized by pulse-like behavior, where only a small part of the fault would rupture at a given instant. This result has been confirmed by a number of inversions of the slip-rate field for large earthquakes, such as the 1992 Landers earthquake in California (Cohee and Beroza, 1994; Wald and Heaton, 1994; Cotton and Campillo, 1995a). Cochard and Madariaga (1996) found that, at least for a simple velocity weakening friction law, heterogeneity could arise spontaneously in a two-dimensional homogeneous fault model as found earlier by Carlson and Langer (1989) for the Burridge and Knopoff model of sliding blocks connected by springs. Other authors studied complex fault models from a theoretical point of view (Harris and Day, 1993, 1997). Beroza and

Mikumo (1996) found that dynamic models with heterogeneous fault parameters tend to generate short slip duration.

In a direct modeling approach, Olsen *et al.* (1997) and Peyrat *et al.* (2001) showed that rupture propagation in a dynamic model of the 1992 Landers earthquake, would follow a complex path, completely controlled by the spatial variation of the initial stress field. Ide and Takeo (1997) estimated the constitutive friction law parameters for the 1995 Kobe earthquake from their kinematic inversion results. Computations of dynamic stress changes for the 1992 Landers, 1994 Northridge, and 1995 Kobe earthquakes (Bouchon, 1997; Day *et al.*, 1998) showed highly variable distributions of stress drops. Spudich *et al.* (1998) detected coseismic changes in the slip direction for the 1995 Kobe earthquake. Nielsen *et al.* (2000) indicated that such complexity inherently arises as a result of many recurrent earthquakes on a single fault over a long time span.

In this chapter we review what we believe are the important results obtained to date in the field of earthquake rupture. In Section 2 we review the early models of earthquake rupture and discuss the elastic shear fault model and fundamental friction laws. We also briefly describe the BIE and FD methods for numerical modeling of dynamic rupture. In Section 3 we illustrate the most important phenomenology of simple rupture models with a single length scale for circular and rectangular fault models, including anisotropy and scaling of growth, generation of sub-shear and super-shear rupture speeds, and the numerical resolution of these models. Scaling laws for earthquake rupture are described in Section 4, including the complementary roles of friction, strength, and geometry. Section 5 shows the results of modeling the 1992 M 7.3 Landers event, including computation of a heterogeneous initial stress field and estimation of the frictional parameters. We compare the dynamic modeling results to those from kinematic models and strong motion data. Finally we discuss the importance of heterogeneity in the rupture process, including the necessity of multiple length scales, generation of self-healing pulses, and the origin of rupture complexity, and discuss the possibility of estimating friction from observations.

2. Fault Models and Friction

In this section we review some of the simpler models that have been used to model seismic ruptures: the Burridge–Knopoff (BK) model; one of its modern versions, the cellular automata (CA) model; and what is still the most useful kinematic description of an earthquake—the dislocation model. Then we introduce the theory behind the elastic shear fault model and basic friction laws. Finally, we briefly describe the concepts of the two numerical methods that have dominated the field of modeling of dynamic rupture: the boundary integral element (BIE) and finite-difference (FD) methods.

2.1 Classical Dynamic Model Assumptions: Burridge–Knopoff and its Successors

Burridge and Knopoff (1967) pioneered dynamic rupture behavior by studying a mechanical model composed of a chain of N blocks coupled by horizontal springs of stiffness κ sliding on a frictional surface that delays the motion of the blocks. The one-dimensional array of springs is connected by individual leaf springs of stiffness k to a rigid driving bar that moves horizontally with a constant velocity. For all reasonable friction laws in which friction decreases once slip starts, the blocks in the BK models move by stick–slip with long periods of stress accumulation and sudden jerky displacement. This model is an analogue or “toy” model of an earthquake fault that is loaded by slow plate motion and locked by friction except in brief intervals when the loading stress overcomes friction at the interface. When this model is loaded at sufficiently high stresses, rupture starts by slip on one of the blocks of the chain and spreads rapidly to neighboring blocks. Until the 1980s this model was a simple and curious analogue to an earthquake rupture, and most seismologists believed that slip episodes would always spread to all the blocks of the system. However, Cao and Aki (1984) and Carlson and Langer (1989) found numerically that this was not the case. Instead, they discovered that very complex rupture histories would develop in this model starting from a nominally homogeneous system. Actually, the BK model has two types of ruptures: Local events that tend to smooth the system; and long events that propagate along the whole chain and wrap around it when cyclic boundary conditions are used. These large, soliton-like events roughen the system, as shown by Schmittbuhl *et al.* (1996). Small events in this system obey a Gutenberg–Richter type power law for the number of events with respect to the number of sliding blocks that participate in any individual event. Large, macroscopic events have a completely different distribution centered around the total number of events in the chain. This model has become a paradigm for the dynamic origin of complexity on a fault, although several authors pointed out a number of reasons why this was not a very realistic model of earthquakes. The most serious problem is that it does not radiate and dissipate seismic energy. Rice and Ben Zion (1996) suggested that small event complexity in this system was probably due to the lack of continuum limit of this model.

An interesting class of models inspired from the BK model, but much simpler to compute, consists of the cellular automata models (see, e.g., Wolfram, 1986). Using different versions of cellular automata, it is possible to reproduce the power law distribution of earthquake statistics (Gutenberg and Richter law). More interestingly, certain interacting dynamical systems may spontaneously evolve into a critical state, producing earthquakes of all sizes. This is the so-called self-organized critical state (see, e.g., Bak *et al.*, 1987). A major problem with cellular automata models is that they lack scales for time and/or length. Time evolution occurs by discrete quasi-static steps so that—at least in the version known to us—they do not include dynamic

effects. As will become apparent in a later section, length and time scales are essential for physically correct modeling of the forces underlying the dynamic behavior. Although these models are for the moment too simple for simulating the observed radiation from a real earthquake, there is no doubt that these concepts will play a major role in future earthquake studies.

In order to understand the physics of the dynamic behavior, we turn to the theory of an elastic shear fault, starting from the simplest approximation.

2.2 The Dislocation Model

In spite of much recent progress in understanding the dynamics of earthquake ruptures, the most widely used models for interpreting seismic radiation are the so-called dislocation models. In these models the earthquake is simulated as the kinematic spreading of a displacement discontinuity (slip or dislocation in seismological usage) along a fault plane. In its most general version, slip in a dislocation model is completely arbitrary and rupture propagation may be as general as desired. In this version the dislocation model is a perfectly legitimate description of an earthquake as the propagation of a slip episode on a fault plane. It must be remarked, however, that not all slip distributions are physically acceptable: as shown by Madariaga (1978), most dislocation models present unacceptable features such as interpenetration of matter, release of unbounded amounts of energy, and so on. For these reasons, dislocation models must be considered as a useful intermediate step in the formulation of a physically acceptable dynamic fault model.

Dislocation models are very useful in the inversion of near-field accelerograms (see, e.g., Cohee and Beroza, 1994; Wald and Heaton, 1994; Cotton and Campillo, 1995a; Mikumo and Miyatake, 1995; and many others). Radiation from a dislocation model can be written as a functional of the distribution of slip on the fault. In a simplified form a seismogram $u(x, t)$ at an arbitrary position x can be written as

$$u(r, t) = \int_0^t \int_{S_\xi} \Delta u(\xi, \tau) G(x - \xi, t - \tau) d\xi d\tau, \quad (1)$$

where $\Delta u(\xi, \tau)$, the slip on the fault, is a function of space and time, and $G(x, t)$ is the Green tensor that may be computed using simple layered models of the crustal structure, or more complex numerical (for example, FD) simulations. Functional (1) is linear in slip amplitude but very nonlinear with respect to rupture propagation, which is implicit in the time dependence of Δu . For this reason, in most inversions the kinematics of the rupture process (position of rupture front as a function of time) is assumed to propagate at constant rupture velocity from the hypocenter. Different approaches have been proposed in the literature in order to invert approximately for variations in rupture speed about the assumed constant rupture velocity (see, e.g., Wald and Heaton, 1984; Cotton and Campillo, 1995a). The slip history on the fault can then be used to compute the history

of stress on the fault by a procedure originally proposed by Mikumo and Miyatake (1979). This method has been used extensively in recent years to estimate the state of stress on a fault (see, e.g., Bouchon, 1997; Ide and Takeo, 1997; Olsen *et al.*, 1997; Day *et al.*, 1998; Guatteri and Spudich, 1998a,b; among many others).

The most important dislocation model was introduced by Haskell (1964). In this model, shown in Figure 1, a uniform displacement discontinuity spreads at constant rupture velocity inside a rectangular-shaped fault. At low frequencies, or wavelengths much longer than the size of the fault, this model is a reasonable approximation to a seismic rupture. In Haskell's model, at time $t=0$ a line of dislocation of width W appears suddenly and propagates along the fault length at a constant rupture velocity until a region of length L of the fault has been broken. As the dislocation moves, it leaves behind a zone of constant slip D . The fault area $L \times W$ times the slip D and the rigidity μ of the medium defines the seismic moment $M_0 = \mu DLW$ of this model. Haskell's model captures some of the most important features of an earthquake and has been used extensively to invert for seismic source parameters from near-field and far-field seismic and geodetic data. The complete seismic radiation for Haskell's model was computed by Madariaga (1978) who showed that, because of the stress singularities around the edges, the Haskell model fails at high frequencies, as was noted by Haskell (1964) himself. All dislocation models with constant slip will have the same problems at high frequencies, although they can be improved by tapering the slip discontinuity near the edges of the fault, as proposed by Sato and Hirasawa (1973). Even better dislocation models can be obtained by taking into account the kinematics of rupture front propagation as proposed by Spudich and Hartzell (1984) and Bernard and Madariaga (1984). Kinematic models have played a mayor role in the quantification of earthquakes and in the inversion of seismic data, a subject that we cannot develop in depth in this chapter.

FIGURE 1 The Haskell kinematic earthquake model, probably the simplest possible earthquake model. The fault has a rectangular shape and a linear rupture front propagates from one end of the fault to the other at constant rupture speed v . Slip in the broken part of the fault is uniform and equal to D .

2.3 Elastic Shear Fault Model

Let us now study the main features of a properly posed source model in a simple homogeneous elastic model of the Earth. Expansion to more complex elastic media, including realistic wave propagation media, poses no major technical difficulties except, of course, that computation time may become very long.

Consider the 3D elastic wave equation:

$$\rho \frac{\partial^2}{\partial t^2} \mathbf{u} = \nabla \cdot \sigma, \quad (2)$$

where $\mathbf{u}(\mathbf{x}, t)$ is the displacement vector field, a function of both position $\mathbf{x}$ and time t , and $\rho(\mathbf{x})$ is the density of the elastic medium. Associated with the displacement field $\mathbf{u}$ the stress tensor $\sigma(\mathbf{x}, t)$ is defined by

$$\sigma = \lambda \nabla \cdot \mathbf{u} \mathbf{I} + \mu [(\nabla \mathbf{u}) + (\nabla \mathbf{u})^T], \quad (3)$$

where $\lambda(\mathbf{x})$ and $\mu(\mathbf{x})$ are Lamé's elastic constants, $\mathbf{I}$ is the identity matrix, and superscript T indicates matrix transpose. We can transform this system into a more symmetric velocity-stress formulation (Madariaga, 1976; Virieux and Madariaga, 1982; Virieux, 1986):

$$\begin{aligned} \rho \frac{\partial}{\partial t} \mathbf{v} &= \nabla \cdot \sigma + \mathbf{f} \\ \frac{\partial}{\partial t} \sigma &= \lambda \nabla \cdot \mathbf{v} \mathbf{I} + \mu [(\nabla \mathbf{v}) + (\nabla \mathbf{v})^T] + \dot{\mathbf{m}}, \end{aligned} \quad (4)$$

where $\mathbf{v}(\mathbf{x}, t)$ is the particle velocity vector, and $\mathbf{f}(\mathbf{x})$ and $\mathbf{m}(\mathbf{x})$ are the force and moment source distributions, respectively.

2.3.1 Boundary Conditions on the Fault

Assume that the earthquake occurs on a fault surface of normal n in the previous elastic medium. Due to frictional instability, a rupture zone can spread along the fault; let $\Gamma(t)$ be this rupture zone at time t . In general, $\Gamma(t)$ is a collection of one or more rupture zones propagating along the fault.

The main feature of a seismic rupture is that, at any point $\mathbf{x}$ inside the rupture zone $\Gamma(t)$, displacement and particle velocities are discontinuous. Let

$$\mathbf{D}(\mathbf{x}, t) = \mathbf{u}^+(\mathbf{x}^+, t) - \mathbf{u}^-(\mathbf{x}^-, t) \quad (5)$$

be the slip vector across the fault, i.e., the jump in displacement between the positive and the negative side of the fault. The notation $\mathbf{x}^\pm$ indicates a point immediately above or below the fault, and $\mathbf{u}^\pm$ are the corresponding displacements.

Slip $\mathbf{D}$ is associated with a *change in the traction* $\mathbf{T} = \sigma \cdot \mathbf{e}_z = [\sigma_{zx}, \sigma_{yz}, \sigma_{zz}]$ across the fault through the solution of the wave equation (4):

$$\Delta \mathbf{T}(\mathbf{x}, t) = \Delta \Sigma[\mathbf{D}] \quad \text{for} \quad \mathbf{x} \in \Gamma(t), \quad (6)$$

where $\Delta \Sigma[\mathbf{D}]$ is a shorthand notation for a functional of $\mathbf{D}$ and its temporal and spatial derivatives.

2.4 Friction

The main assumption in seismic source dynamics is that traction across the fault is related to slip at the same point through a *friction law* that can be expressed in the general form

$$\mathbf{T}(\mathbf{D}, \dot{\mathbf{D}}, \theta_i) = \mathbf{T}_{\text{total}} \quad \text{for} \quad \mathbf{x} \in \Gamma(t) \quad (7)$$

such that friction $\mathbf{T}$ is a function of at least slip, but an increasing amount of experimental evidence shows that it is also a function of slip rate $\dot{\mathbf{D}}$ and several state variables denoted by θ_i , $i = 1, \dots, N$. The traction that appears in friction laws is the total traction $\mathbf{T}_{\text{total}}$ on the fault, which can be expressed as the sum of preexisting stress $\mathbf{T}^0(\mathbf{x})$ and the stress change $\Delta \mathbf{T}$ due to slip on the fault obtained from Eq. (6). The prestress is caused by tectonic load of the fault and will usually be a combination of purely tectonic loads due to internal plate deformation, plate motion, etc., and the residual stress field remaining from previous seismic events on the fault and its vicinity.

Using Eq. (6), we can now explicitly formulate the friction law on the fault [Eq. (7)]:

$$\mathbf{T}(\mathbf{D}, \dot{\mathbf{D}}, \theta_i) = \mathbf{T}^0(\mathbf{x}) + \Delta \mathbf{T}(\mathbf{x}, t) \quad \text{for} \quad \mathbf{x} \in \Gamma(t) \quad (8)$$

Friction as defined by Eq. (8) is clearly a vector. For the appropriate study of a shear fault we need to write Eq. (8) as a system of two equations. Archuleta and Day (1980), Day (1982a,b), and Spudich (1992) used a very simple approach that will certainly have to be refined in the future, assuming that slip rate and traction are antiparallel, i.e.,

$$\mathbf{T}(\mathbf{D}, \dot{\mathbf{D}}, \theta_i) = -T(D, \dot{D}, \theta_i) \mathbf{e}_V, \quad (9)$$

where $\mathbf{e}_V = \dot{\mathbf{D}} / \|\dot{\mathbf{D}}\|$ is a unit vector in the direction of instantaneous slip rate. With this assumption, the boundary condition reduces Eq. (8) to the special form

$$-T(D, \dot{D}, \theta_i) \mathbf{e}_V = \mathbf{T}^0(\mathbf{x}) + \Delta \mathbf{T}(\mathbf{x}, t) \quad \text{for} \quad \mathbf{x} \in \Gamma(t). \quad (10)$$

Figure 2a shows the vector diagram implied by this equation. The only fixed vector in this diagram is the prestress, which is assumed to be known. Friction and slip rate are collinear but antiparallel. Stress change $\Delta \mathbf{T}$ is in general collinear neither with prestress nor with friction. Recently, Spudich (1992), Cotton and Campillo (1995b), and Guatteri and Spudich (1998b) analyzed expression (10) and studied several recent earthquakes, showing that slip directions were not always parallel to stress drop. These rake rotations may also have information about the absolute stress levels (Spudich, 1992; Guatteri and Spudich, 1998b).

In most rupture models the above "vector" friction is simplified to a "scalar boundary condition," in which slip is only allowed in the direction of the initial stress, which is everywhere parallel to the x axis, i.e., $\mathbf{T}^0(\mathbf{x}) = [T_x^0(\mathbf{x}), 0]$ and $\mathbf{D}(\mathbf{x}, t) = [D_x(\mathbf{x}, t), 0]$; then the scalar components are simply related by

$$\Delta T_x(\mathbf{x}, t) = T(D, \dot{D}, \theta_i) - T_x^0(\mathbf{x}) \quad \text{for} \quad \mathbf{x} \in \Gamma(t). \quad (11)$$

FIGURE 2 Diagram showing the relation between initial stress, slip rate, friction, and traction change for the vector (a) and scalar (b) approximations to friction on the fault plane. In the scalar case, traction change corresponds to the usual definition of stress drop. (Reproduced with permission from Madariaga *et al.*, 1998; fig. 1, p. 1185.)

This boundary condition, which may be graphically described as if the fault had “rails” aligned in the x direction, has been applied in most 3D source models, starting with Madariaga (1976).

2.5 Friction Laws

Both boundary conditions (10) and (11) require a friction law that relates scalar traction T to slip, its derivatives, and possible state variables. For more details, see Dieterich (1978, 1979) and Rice and Ruina (1983), but see also Ohnaka (1996) for an alternative point of view.

Let us first discuss the simple slip weakening friction law introduced by Ida (1972). It is an adaptation to shear faulting of the Barenblatt–Dugdale friction laws used in hydrofracturing and tensional (mode I) cracks. In this friction law, slip is zero until the total stress reaches a peak value (yield stress) that we denote by T_u . Once this stress has been reached, slip D starts to increase from zero and $T(D)$ decreases linearly to zero as slip increases:

$$\begin{aligned} T(D) &= T_u \left(1 - \frac{D}{D_c} \right) + T_f & \text{for } D < D_c \\ T(D) &= T_f & \text{for } D > D_c, \end{aligned} \quad (12)$$

where D_c is a characteristic slip distance and T_f is the residual friction at high slip rate, sometimes called the “kinematic” friction. There is a lot of discussion in the literature about how large this residual friction is. Many authors, following the observation that there is a very broad heat flow anomaly across the San Andreas fault in California, have proposed that faults are “weak,” meaning that T_f is close to zero. Other authors propose that kinematic friction is high and faults are strong. We cannot go into any detail about this discussion here: interested readers may consult the papers by Scholz (2000) and Townend

and Zoback (2000). For most applications of earthquake dynamics, only stress change is important, so that without loss of generality we can assume that $T_f = 0$ in much of the following. Let us remark, however, that Spudich (1992), Guatteri and Spudich (1998a), and Spudich *et al.* (1998) have found some evidence for absolute stress levels from nonparallel stress drop and slip of the 1995 Kobe earthquake in Japan.

The slip weakening friction law (12) has been used in numerical simulations of rupture by Andrews (1976a,b), Day (1982b), Harris and Day (1993), Fukuyama and Madariaga (1998), Madariaga *et al.* (1998), and many others. Slip weakening at small slip is *absolutely necessary for the friction law to be realizable*, otherwise stress would become unbounded near the rupture front, violating energy conservation so that seismic ruptures could only spread at either S , Rayleigh, or P wave velocities until they stop. Of course, in numerical implementations stress is never infinite, so that rupture velocity is numerically limited. In many earlier studies of earthquake dynamics, a simpler version of Eqs. (12) was used in which D_c was effectively zero. This numerical version of slip-weakening has been called the Irwin criterion by Das and Aki (1977a) and has been widely used by many authors although it is obviously grid-dependent (see, e.g., Virieux and Madariaga, 1982).

Once slip is larger than the slip weakening distance D_c , friction becomes a function of slip rate $\dot{D}$ and one or more state variables that represent the memory of the interface to previous slip. A very simple *rate-dependent friction law* was proposed by Burridge and Knopoff (1967) and has been used extensively in simulations by Carlson and Langer (1989) and their colleagues and by Cochard and Madariaga (1986):

$$T(\dot{D}) = T_s \frac{V_0}{V_0 + \dot{D}} + T_f, \quad (13)$$

where V_0 is a characteristic slip velocity and $T_s \leq T_u$ is the limit of friction when slip rate decreases to zero. The applicability of rate weakening to seismic ruptures is much more controversial than slip weakening, although there is plenty of indirect evidence for its presence in seismic faulting. Heaton (1990) proposed that it was the cause of short rise times; rate-dependence at steady slip velocities is also an intrinsic part of the friction laws proposed by Dieterich (1978) and Ruina (1983), which will be reviewed in the following.

The slip weakening and slip rate weakening behavior described above can be combined if for any value of D and $\dot{D}$ the larger of expressions (12) and (13) is selected. Instead of writing a complex expression, it is simpler to show the friction law graphically in Figure 3 in the form of a law where friction depends on the two state variables slip and slip rate. The friction law described above allows rupture propagation that is completely controlled by the complex nonlinear interaction of

1. The initial stress field T^0 in (8).
2. The distribution of yield frictional resistance T_u in Eqs. (12) and (13).
3. The parameters D_c , T_s , and V_0 of the friction laws in Eqs. (12) and (13).

As mentioned earlier, most recent work on friction has been concentrated in a class of friction laws that depend both on slip rate and state variables. These laws were developed from laboratory experiments at low slip rates by Dieterich (1978, 1979) and Ruina (1983).

Typically, a rate-and-state dependent friction law can be expressed by

$$T(\dot{D}, \theta) = \theta + \tau(\dot{D}), \quad (14)$$

where $\tau(\dot{D})$ is the instantaneous response of friction to slip rate changes (“the direct effect”). The state variable θ represents the weakening of the interface with time and in general it is considered to satisfy an evolution equation of the form

$$\dot{\theta} = \frac{V_0}{L} G(\dot{D}, \theta). \quad (15)$$

Here L is a *weakening distance* that measures how much slip will occur before the friction weakens to the steady state value; V_0 is a reference slip rate. There are many versions of these friction laws, but the main features are not very different from slip weakening, at least at the high slip rates that occur near the rupture front. Computations by Dieterich and Kilgore (1996) show that the slip weakening distance for rate-and-state dependent friction is roughly $D_c \simeq 4L$, an approximation also found by Gu and Wong (1991). Although rate-and-state dependent friction is very important for the study of rupture initiation and repeated ruptures on a fault surface, its features are indistinguishable from simpler slip-dependent and rate-dependent friction laws during the dynamic part of seismic ruptures.

2.6 The Boundary Integral Element Method

An essential requirement in studying dynamic faulting is an accurate and robust method for the numerical modeling of wave

FIGURE 3 Slip- and slip rate-dependent friction law. For values of stress less than the peak static friction (T_u), slip and slip rate are zero. Once slip begins, stress is a function of both slip and slip rate described by the friction surface $T(D, \dot{D})$. Slip weakening is measured by D_c , rate weakening by V_0 . The continuous curve shows the typical stress trajectory of a point on the fault. (Reproduced with permission from Madariaga *et al.*, 1998; fig. 2, p. 1185.)

propagation that can also accurately handle the nonlinear boundary conditions on the fault surface. One of the important methods is the boundary integral equation (BIE) method. The BIE method was pioneered in 2D by Das and Aki (1977a,b) in the so-called direct version. It was later extended to 3D by Das (1980, 1981) and improved by Andrews (1985). A new version of the BIE method, the so-called indirect, or displacement discontinuity, method, was proposed by Koller *et al.* (1992). The indirect method was improved by the removal of strong singularities by a number of authors (e.g., Fukuyama and Madariaga, 1995, 1998; Geubelle and Rice, 1995; Cochard and Madariaga, 1996; Bouchon and Streiff, 1997). Following Fukuyama and Madariaga (1998), the integral equations for a shear fault can be expressed as

$$\begin{aligned}
 T_\alpha(x_1, x_2, t) &= \frac{3\mu}{\pi} \int_{S^+} \int_{S^+} \frac{r_{,\alpha}}{r^2} \int_1^\kappa \tau D_{\beta,\beta}(\xi_1, \xi_2, \|t - vr/c_T\|) d\tau d\xi_1 d\xi_2 \\
 &+ \frac{5\mu}{4\pi} \int_{S^+} \int_{S^+} \frac{r_{,\alpha}}{r^2} D_{\beta,\beta}(\xi_1, \xi_2, \|t - r/c_T\|) d\xi_1 d\xi_2 \\
 &- \frac{\kappa^2\mu}{\pi} \int_{S^+} \int_{S^+} \frac{r_{,\alpha}}{r^2} D_{\beta,\beta}(\xi_1, \xi_2, \|t - r/c_L\|) d\xi_1 d\xi_2 \\
 &- \frac{\mu}{4\pi} \int_{S^+} \int_{S^+} \frac{r_{,\beta}}{r^2} D_{\alpha,\beta}(\xi_1, \xi_2, \|t - r/c_T\|) d\xi_1 d\xi_2 \\
 &+ \frac{\mu}{4c_T\pi} \int_{S^+} \int_{S^+} \frac{r_{,\alpha}}{r} \dot{D}_{\beta,\beta}(\xi_1, \xi_2, \|t - r/c_T\|) d\xi_1 d\xi_2 \\
 &- \frac{\mu}{2c_T} \dot{D}_\alpha(x_1, x_2, t), \tag{16}
 \end{aligned}$$

where $D_{i,j}$ is the derivative with respect to T of the i th component of slip and the “dot” denotes the time derivative, μ is rigidity, c_L and c_T are P - and S -wave velocities, respectively, $\kappa = c_T/c_L$, ρ is density, $r = |\mathbf{x} - \mathbf{x}_i|$, $r_{,i} = (x_i - \xi_i)/r$, and $\|a\|$ is a shorthand notation meaning that the slip functions D are evaluated only for positive values of a . S^+ represents the upper surface of the crack. The Greek indices α and β can be either 1 or 2. Each term in this system of boundary integral equations has a simple interpretation. The first four terms are near-field effects due to the horizontal gradient of slip. The fifth term represents “far-field” or high-frequency S -wave radiation. The last term is the radiation damping due to the emission of S -waves in the direction normal to the fault. In order to solve the integral equation (16) numerically for shear faults, a discretization using interpolation functions has to be introduced. Traditionally in BIE high-order spatial interpolation and very low-order interpolation in time are adopted (see, e.g., Hirose and Achenbach, 1989; Koller *et al.*, 1992). This was the method adopted for antiplane cracks by Cochard and Madariaga (1996) or by Fukuyama and Madariaga (1995, 1998) for 3D faulting. Since high-order spatial interpolations lead to implicit equations in time that are almost impossible to solve in the presence of nonlinear friction on the fault, several implementations use simpler piecewise constant interpolation of slip velocity. This

leads to a formulation of crack problems that Cruse (1988) calls the displacement discontinuity method. With this interpolation, the slip gradient $D_{\beta,\alpha}$ is sharply localized at the boundaries of the grid elements.

BIE methods are excellent for the study of earthquake initiation and the transition from accelerated fault creep to fully dynamic rupture propagation. A problem with the BIE method for the simulation of dynamic earthquake ruptures is the relatively large requirement for computer memory (though not of computer time) and a need for explicit computation of the operator $\Delta\mathbf{\Sigma}$. Also, at least in their current implementations, BIE methods cannot be used in heterogeneous media, but can be used for complex fault geometries and homogeneous half-spaces. Aochi *et al.* (2000) have recently extended the BIEM to handle complex faults with noncoplanar segments. They studied rupture propagation for the 1992 Landers earthquake and showed that rupture can jump between segments under some restrictive conditions.

2.7 The Finite Difference (FD) Method

The other numerical method widely used for numerical modeling of dynamic wave propagation is the finite difference (FD) method. The FD method was introduced by Madariaga (1976) and Andrews (1976a,b) for the study of seismic ruptures and was developed by numerous authors (e.g., Miyatake, 1980, 1992; Day, 1982a,b; Mikumo *et al.*, 1987; Harris and Day, 1993; Olsen *et al.*, 1997; Madariaga *et al.*, 1998). The method can be used to study rupture propagation in heterogeneous elastic media and is very efficient. An advantage of finite differences is that the operator $\Delta\mathbf{\Sigma}$ in Eq. (6) does not have to be computed explicitly. In the FD method, all that is needed is a numerical procedure that computes the stress change $\Delta\mathbf{T}$ given the slip distribution $\mathbf{D}$ at earlier times.

Numerous different implementations of the FD method have been presented in the literature, and it is beyond the scope of this chapter to cover them all. In general, FD methods used to model earthquakes can be divided into two types. The first type derives from the direct discretization of the second-order PDE obtained by substituting Eq. (3) into Eq. (2). Methods of this kind were derived and greatly developed by Mikumo and Miyatake (1979), Miyatake (1980), Mikumo *et al.* (1987), and Mikumo and Miyatake (1993). The other approach, the staggered grid velocity–stress formulation, was developed by Madariaga (1976) to study dynamic rupture problems and is based on the discretization of the system of Eq. (4). The staggered grid method is characterized by low numerical dispersion and the fact that no derivatives of media parameters are needed. The latter is a strong advantage over FD implementations of the second-order displacement formulation of the wave equation where accuracy is lost in the computation of derivatives of media parameters near significant gradients in the model. Olsen *et al.* (1995a) and Olsen and Archuleta (1996) demonstrated the efficiency of the fourth-order formulation of the velocity–stress

FIGURE 4 A cubic element of the 3D finite difference grid used in the dynamic modeling of a planar shear fault. σ and v depict the components of the stress tensor and particle velocity, respectively. (Reproduced with permission from Madariaga *et al.*, 1998; fig. 9, p. 1192.)

method by computing wave propagation around a kinematically defined rupture in a large-scale 3D model.

The velocity–stress FD method is illustrated in Figure 4; stress and velocities are defined at alternating half-integer time steps. At time $t_N = N \Delta t$, particle velocity v is computed from previously calculated stress components. At the next half-time step $t_{N+1/2} = (N + \frac{1}{2}) \Delta t$, stress σ is updated using the velocity field computed at time t_N . Thus as time increases, velocities and stresses are computed at alternate times. Because stress and velocities are computed from Eq. (4) using centered fourth-order finite differences, the grid is also staggered spatially as shown in Figure 4. Madariaga *et al.* (1998) extended the FD method presented by Olsen (1994), Olsen *et al.* (1995a), and Olsen and Archuleta (1996) in order to study dynamic rupture propagation on a planar shear fault embedded in a heterogeneous half-space. We will use their “thick fault” boundary condition to illustrate important dynamic rupture phenomenology in this section, although alternate implementations exist. Current developments include the coupling of a BIE solution for slip and stress on the fault to a finite difference computation of radiated waves (Olsen *et al.*, 2000).

3. Phenomenology of Rupture Models with a Single Length Scale

We start the study of seismic ruptures from a very simple earthquake model that is a sort of classic test model inspired by Kostrov’s (1964) study of a self-similar circular shear crack. We study the spontaneous propagation of a seismic rupture starting from a circular asperity that is ready to break. The asperity is

surrounded by a fault surface uniformly loaded at a stress level that is less than the peak stress in the slip weakening friction law [Eq. (12)]. These are very similar conditions to those used by Day (1982b) and Das (1981) to start rupture. There are two main reasons to proceed this way: First, if the asperity is too small, rupture will start and stop immediately. For rupture to expand, stress must be high over a finite zone, sometimes called the minimum rupture patch. The other reason why rupture has to start from a finite-size asperity is that, if the stress field were uniform, rupture would occur instantaneously or grow at the maximum possible velocity from an arbitrary point on the fault. This is unrealistic and not supported by observations. Finally, it is assumed that fault rupture must occur at stress levels that are below the yield stress except for a small number of isolated asperities. In the following examples there is only one such asperity, even though rupture starting from several locations is possible (e.g., Day, 1982b; Olsen *et al.*, 1997).

3.1 Dimensional Analysis

The following discussion uses nondimensional variables. This has the advantage of clearly showing how different variables scale with stresses and distances. We choose the following dimensional variables:

- Distances along the fault are measured in units of Δx , the grid interval.
- Wave velocities are measured in units of β , the shear wave velocity.
- Stress is measured in units of T_u , the peak frictional resistance (yield stress) in the friction laws described in Eqs. (12) and (13).

All other dimensions are determined by the previous three. In particular:

- Time is measured in units of $\Delta t = H \Delta x / \beta$, where β is the shear wave velocity. H is the so-called CFL (Courant–Friedrich–Lewy) parameter that controls stability of the numerical method. In our simulations it was usually taken as 0.25 in order to insure stability and sufficient accuracy.
- Displacement is measured in units of $T_u / \mu \times \Delta x$.
- Particle velocities are measured in units of $T_u / \mu \times \beta$.

Slip and slip rate are normalized by $2T_u / \mu \times \Delta x$ and $2T_u / \mu \times \beta$. The factor of 2 is not really necessary but follows a tradition in seismological publications. It is also assumed that the P -wave velocity α is equal to $\sqrt{3}\beta$. Finally, D_c , the slip weakening distance in Eq. (12) is measured in units of slip (i.e., $2T_u / \mu \times \Delta x$), and V_0 , the rate weakening parameter, is measured in units of slip rate (i.e., $2T_u / \mu \times \beta$). We have followed seismological tradition and used the grid length, Δx , to scale fault length, instead of a physical length such as the slip weakening distance D_c . The reason is that until recently most simulations

of 3D seismic ruptures used a grid-dependent fracture criterion introduced by Das and Aki (1977a).

3.2 A Circular Fault Model

In our first model we study rupture propagation where the initial stress distribution is symmetric about the origin. We force rupture to stop once it reaches a circular distance R . Rupture resistance, represented by T_u and D_c , is perfectly uniform. We initiate the rupture from a finite asperity of radius R_{asp} . Rupture velocity is not constant but is determined from the friction law. Our solutions are not self-similar and, as already illustrated by Das (1981), Day (1982b), Virieux and Madariaga (1982), and others, spontaneous ruptures do not maintain simple elliptical shapes as they grow.

The circular fault has a radius $R = 50 \times \Delta x$, starting from a concentric asperity of radius $R_{asp} = 6 \times \Delta x$, $D_c = 4$, and stress inside the asperity was $T_{asp} = 1.2 \times T_u$ and $T_{ext} = 0.8 \times T_u$ outside. Snapshots of the slip rate are shown in Figure 5 at

several successive instants of time. Time is measured in units of $\Delta t = H \Delta x / \beta$, where $H = 0.25$ as discussed earlier. From time steps $t = 17.5$ to 35, rupture is taking place inside the asperity, and is propagating away from the asperity for $t > 52.5$. We observe that rupture becomes spontaneously elongated in the vertical direction, which is also the direction of the initial stress. Thus, as already remarked by Das (1981) and Day (1982b), rupture tends to grow faster in the in-plane direction, which is dominated by mode II.

At time $t = 87.5$, rupture in Figure 5 has reached the unbreakable border of the fault in the in-plane direction, and at time $t = 105$ the stopping phases generated by the upper and bottom edges of the fault are moving toward the center of the fault. The snapshots after $t = 122.5$ show stopping phases propagating inward from all directions. The slipping patch in darker shading is now elongated in the antiplane direction, which is due to slower healing. At time $t = 140$ the in-plane stopping phases (moving in the vertical direction) have already reached the center of the fault and crossed each other. In the

FIGURE 5 Snapshots of slip rate at successive instants of time for the spontaneous rupture of an overloaded asperity inside a circular fault (solid line). The nondimensional time for each snapshot is shown below each picture. (Reproduced with permission from Madariaga *et al.*, 1998; fig. 9, p. 1192.)

last two snapshots, rupture continues in a small patch near the center of the fault that coincides with the initial asperity. However, slip rate has decreased to such small values that it is very likely contaminated with numerical noise.

3.3 Rectangular Fault

Now we turn to a model that starts in the same way as the circular fault from an overloaded asperity. However, here the unbreakable barrier forces rupture to expand in essentially one direction along a rectangular fault. We build this model as a prototype of rupture along a shallow strike-slip fault and use similar values for the friction laws as those for the circular crack simulation ($H=0.2$; slip weakening distance $D_c=4$; initial stress inside and outside the asperity $T_{asp}=1.2 \times T_u$ and $T_{ext}=0.8 \times T_u$, respectively; radius of the initial asperity $R_{asp}=6 \times \Delta x$; for the rate-weakening simulations we used $V_0=0.03$ and $T_s=T_u$). Unfortunately, as pointed out by Heaton (1990) and discussed by Cochard and Madariaga (1996), there is no information about velocity weakening at

high slip rates. The value chosen for V_0 is arbitrary and corresponds to rapid healing when slip rate becomes about 3% of the peak slip rate.

Color Plate 3 shows snapshots of the slip rate on the fault plane for simulations using slip weakening and rate weakening friction, respectively. The prestress on the fault is directed along the vertical (long) axis of the fault. In the simulation of part (a) with slip weakening but no rate weakening, we see the rupture emerging from the asperity with relatively slow healing (long “tail” trailing from the front). Rupture starts out slowly, accelerates toward the S -wave speed and, at a mature stage near time $t=80$, suddenly “jumps” to the P -wave speed. The transition to supershear rupture speeds is an instability that develops from the in-plane direction and spreads laterally along the rupture front, producing a “bulge” observed in the snapshots after $t=80$. Stopping phases emitted from the sides of the fault clearly control the duration of slip, as shown in snapshots at $t=120$ through 160. In the snapshot at $t=160$, the stopping phases have reached the center of the fault just below the time label 160.

FIGURE 6 Final stress without (a) and with (b) rate weakening, and final slip without (c) and with (d) rate weakening, for the simulations shown in Color Plate 3(a) and (b). The plots clearly show a decrease in slip as well as the development of stress heterogeneity inside the fault due to rate weakening. (Reproduced with permission from Madariaga *et al.*, 1998; fig. 12, p. 1195.)

The situation is quite different with the use of a rate-dependent friction law, where the slip rate tends to concentrate in narrow patches (Part b). Compared to Part (a), the rupture front is narrower and clearly delineated. Well before the arrival of stopping phases from the sides of the fault, slip rate has become very small near the center of the asperity. Rupture takes the shape of a band. As time increases and rupture is controlled by the edges of the fault, the rupture front becomes narrow and localized. This is similar to the behavior predicted by Heaton (1990).

The other major difference introduced by rate-dependent friction is that, behind the rupture front, stress becomes heterogeneous. It appears that the rupture leaves a wake of complexity after its passage. This complexity is apparent in the distributions of both slip (Fig. 6c,d) and stress drop (Fig. 6a,b). The development of stress heterogeneity in the wake of the rupture front is an essential feature of rate weakening as proposed by Carlson and Langer (1989) for the BK model. It was shown by Cochard and Madariaga (1996) that stresses become complex because rate weakening promotes early healing of the fault. When the fault heals rapidly, all heterogeneities become frozen on the fault and cannot be eliminated until the fault slips again. This process of generating heterogeneity was similar to what Bak *et al.* (1987) had in mind when they proposed that earthquakes were an example of self-organized criticality. Finally, note that the faster healing caused by rate weakening friction decreases the slip significantly.

3.4 Numerical Resolution and Scaling with the Slip Weakening Distance

An essential requirement for an accurate numerical method is that the numerical solution becomes independent of grid size beyond the use of a certain number of grid points per wavelength. The shortest physical distances are the radius of the asperity R and the width of the rupture front. The latter depends on the slip weakening distance D_c as shown by Ida (1972), Andrews (1976b), and Day (1982b). For 2D faults and for the slip weakening law (12) this width, L_c , is

$$L_c = \frac{4\mu}{3\pi} \frac{T_u}{T_{\text{ext}}^2} D_c \quad (17)$$

We have assumed that the residual friction at high slip rates in Eq. (12) ($T_f = 0$) is zero. This expression is valid for a constant stress level T_{ext} outside the asperity.

In order to describe the convergence of the numerical method as the grid size is refined, consider a simple circular asperity, keeping all the parameters constant except the grid size and D_c . Stress inside the asperity is $T_{\text{asp}} = 1.8 \times T_u$, $T_{\text{ext}} = 0.8 \times T_u$ and $H = 0.20$. Replacing T_{ext} in Eq. (17) gives $L_c = 1.36 \times D_c$. Figure 7 shows snapshots of the slip rate as a function of position on the fault at equivalent instants of time. Since Δx is used as the scaling distance, both the

FIGURE 7 Scaling of rupture at constant load for spontaneous rupture starting from an overloaded asperity. The four snapshots show the distribution of slip rate on the fault at equivalent times for four different values of D_c . The initial asperity radius R as well as the instant of time of the snapshot all scale with D_c . (a) $D_c = 2$, $R = 3$, and $T = 140$; (b) $D_c = 4$, $R = 6$, and $T = 280$; (c) $D_c = 6$, $R = 9$, and $T = 420$; (d) $D_c = 8$, $R = 12$, and $T = 560$. (Reproduced with permission from Madariaga *et al.*, 1998; fig. 6, p. 1186.)

radius of the asperity R as well as the time of the snapshot have to be increased for increasing values of D_c . The four parts of the figure show snapshots for (a) $t = 140$ ($D_c = 2$, $R = 3$), (b) $t = 280$ ($D_c = 4$, $R = 6$), (c) $t = 420$ ($D_c = 6$, $R = 9$), and (d) $t = 560$ ($D_c = 8$, $R = 12$). The external rectangles define the size of the grid, 256×256 for D_c from 2 to 6 and 300×256 for $D_c = 8$. Note the scaling of the figures—the snapshot for $D_c = 8$ is precisely twice as large as that for $D_c = 4$. Clearly, the degree of resolution improves as D_c increases.

From a close examination of these snapshots and several others, we concluded that fourth-order finite difference simulations are contaminated by numerical noise when $D_c < 4\Delta x$, and that numerical simulations are stable and reproducible for $D_c > 6\Delta x$ ($L_c > 7\Delta x$). For 3D simulations, this is a rather large number that requires the use of very dense grids for accurate simulation of spontaneous rupture.

4. Earthquake Scaling Laws

In the previous section we illustrated spontaneous rupture starting from a circular asperity of radius R_{asp} that is ready to break (with stress T_u) and is surrounded by a fault surface. For convenience in numerical modeling, we scaled all physical

quantities by the grid interval Δx . Obviously this is not satisfactory in actual applications to earthquakes. The first earthquake scaling law was proposed by Aki (1967), who pointed out a relation between magnitudes at 1 Hz and at 20 sec, assuming that all earthquakes have a similar spectrum that depends on a single scaling variable, the size of the fault. This scaling law was later reformulated by Brune (1970) in the form of a universal shape for the spectrum of S -wave radiation.

The scaling laws can be derived by a simple dimensional analysis of the boundary value problem for an earthquake source in a uniform, infinite elastic medium. In such a simple medium there are only three independent physical dimensions: a length or geometric scale, a stress or dynamic scale, and the time scale. In elastodynamics the time scale is not independent of the length scale, since the two are connected by the speed of elastic waves. Adopting the shear wave speed β as the scale for velocities, and a measure of stress drop $\Delta\sigma$ as the stress scale, the only other free dimension is a length scale for the fault. The appropriate choice for the length scale is the overall size of the fault, its radius for a circular fault, or a characteristic dimension of stress distribution for complex sources. Once these variables are fixed, all other parameters can be scaled with respect to them. Thus, for instance, slip on the fault must scale like the characteristic length L times the ratio of the characteristic stress drop $\Delta\sigma$ to the elastic constant μ . Similarly, slip rate on the fault scales as the same ratio $\Delta\sigma/\mu$ times the wave speed β . All other physical quantities can be derived from these as shown in Table 1.

Studies of many earthquakes under completely different tectonic conditions, for shallow and deep sources, show that stress drop varies over at most two orders of magnitudes, while L varies over a wide range. As a consequence, seismic moment M_0 scales roughly with the cube of the fault size L for moments 10^{10} – 10^{21} N m (moment magnitude $M_W = 8.0$). Beyond this magnitude there are serious uncertainties in the

scaling law, but it is likely that very large earthquakes scale differently, in particular where ruptures are limited to a narrow zone near the surface of the Earth.

4.1 Other Length Scales

We have already seen in the discussion of numerical modeling that overall fault size is not the only length scale that is important in understanding earthquakes. The minimum slip patch—the minimum coherent zone of the fault that may rupture dynamically—is an important independent characteristic size of earthquake sources. Like all other length scales, this minimum patch size scales directly with the slip weakening distance D_c , the minimum slip necessary for friction to reduce to the kinematic friction on the fault. The exact nature of D_c is subject to debate, but the existence of such a length is absolutely necessary for the rupture problem to be physically well posed. Estimates of D_c and its associated minimum patch length scale $l = (\mu/\Delta\sigma)D_c$ vary widely, but it must be a small fraction of the overall length L . According to some authors, D_c is a property of the friction law to be determined from experiments on rock friction (see, e.g., Dieterich, 1978, 1979; Ruina, 1983); for others, D_c scales with the roughness of the fault surfaces, which in turn scales with earthquake size (Ohnaka and Kuwahara, 1990; Ohnaka and Shen, 1999). These two very opposite views emphasize different properties of earthquakes. For those authors who believe that D_c is a property of the fault zone, a universal friction law that describes the tribology of the fault must exist independently of the final size of the earthquake. This is consistent with most friction experiments carried out by the school of Dieterich, Ruina, and others.

For other authors, D_c is the result of rupture scaling over a broad range of magnitudes. Large earthquakes can occur only if D_c becomes large; otherwise they simply stop as first proposed by Aki (1979). Unfortunately it is not possible to settle this argument from seismic data alone because of the lack of high-quality near-field strong motion records. The current resolution of near-field observations is about 0.5 Hz, which translates into a shear wavelength of the order of 6–7 km and a slip weakening distance of $D_c \simeq 10$ cm (Ide and Takeo, 1997; Olsen *et al.*, 1997; Day *et al.*, 1998; Guatteri and Spudich, 1998b). This is too coarse to detect any scaling of D_c with earthquake size at the present time.

4.2 Scaling of Energy and Rupture Resistance

The previous discussion indicates that earthquake phenomena cannot be characterized by a single length scale unless, of course, the slip weakening distance scales with the size of the earthquake. Let us explore some of the consequences of small-size scaling for rupture dynamics through a simple fracture model.

Let us define rupture resistance, or energy release rate, which for the simple slip weakening friction model (12) is

TABLE 1 Scaling of Different Physical Quantities from a Simple Fault Model as a Function of the Three Fundamental Parameters Length, Stress Drop, and Shear-wave Speed^a

Variable	Symbol	Expression
Length	L	
Stress drop	$\Delta\sigma$	
Shear wave speed	β	
Slip	D	$\Delta\sigma/\mu \times L$
Slip rate	$\dot{D}$	$\Delta\sigma/\mu \times \beta$
Fault surface	S_0	L^2
Duration of radiation	T	L/β
S -wave corner frequency	f_c^S	β/L
P -wave corner frequency	f_c^P	α/L
Seismic energy	E_s	$\Delta\sigma^2/\mu \times L^3$
Seismic moment	M_0	$\Delta\sigma L^3$
Fracture energy	G	$\Delta\sigma D_c$

^a Other groups of three fundamental units can be chosen, but this is the standard choice in seismology.

given by

$$G = \frac{1}{2} T_u D_c. \quad (18)$$

This is the amount of energy that is needed to produce a unit area of slipping fault. In most fracture studies G is assumed to be a material property. However, Ohnaka and Shen (1999) present strong evidence that this may not necessarily be the case.

4.2.1 Rupture Initiation

A sensitivity analysis of the effect of changing rupture resistance on rupture propagation made by Madariaga and Olsen (2000) shows that there are two regimes that are controlled by a single nondimensional number:

$$\kappa = \frac{T_e^2}{\mu T_u} \frac{R_{\text{asp}}}{D_c}, \quad (19)$$

where R_{asp} is the radius of the minimum asperity size (Madariaga and Olsen, 2000). This parameter can be derived from Andrews's (1976a) relation (17). As shown by Madariaga and Olsen (2000), using the calculations of Andrews (1976a), κ is a measure of the ratio of available strain energy ΔW to energy release rate G defined in Eq. (18). The strain energy change in a zone of radius R , uniformly loaded by an initial stress T_e is

$$\Delta W = \frac{1}{2} \langle D \rangle T_e \simeq \frac{T_e^2}{\mu R}, \quad (20)$$

where $\langle D \rangle$ is the average slip on a fault of radius R and stress drop T_e . Thus $\kappa \simeq \Delta W/G$. An essential requirement for rupture to grow beyond the asperity is that $\kappa > \kappa_c$, where the critical value of κ for the circular asperity can be derived from the study by Madariaga and Olsen (2000), who computed numerically the critical radius R_c for fixed T_u , T_e , and D_c . They found that

$$\kappa_c = 0.60. \quad (21)$$

κ_c defines a bifurcation of the problem as a function of parameter κ . Another estimate of κ_c was obtained earlier by Day (1982a,b), who found $\kappa_c = 0.91$. The reason Day's estimate is larger than ours is that Day assumed that rupture could start only when energy balance around the whole perimeter of the asperity allowed rupture to start. As shown by Das and Kostrov (1983), however, rupture may start from the edge of the asperity and then surround the fault before breaking away from the asperity. For $\kappa < \kappa_c$, rupture does not grow beyond the initial asperity. For $\kappa > \kappa_c$, rupture grows indefinitely at increasing speed. This is a simple example of a pitchfork bifurcation.

There is a complication, however: as shown by Andrews (1976b), the rupture front makes a sudden jump to speeds larger than the shear wave speed if T_{ext} is larger than a certain fraction of the peak stress drop T_u . Transition to super-shear

speeds is a complex bifurcation that needs much further study. Andrews (1976b) found that the jump to super-shear speed was due to the formation of a stress peak that runs at the shear wave speed ahead of the rupture front. This mechanism does not seem to operate for the transitions observed in 3D by Madariaga and Olsen (2000). In any case, super-shear ruptures in mode II (in-plane shear) are well documented by a number of experiments made by Rosakis *et al.* (1999). Madariaga and Olsen showed that the jump to super-shear speed occurs for a value of $\kappa > 1.3\kappa_c$; further discussion of this issue may be found in their paper. A final important remark is that the problem of rupture propagation from an initial asperity in a homogeneous medium under uniform stress has no other nondimensional control number than κ because this problem has exactly the five independent parameters that appear in the expression for κ . Andrews (1976b) used a different way of plotting the condition for rupture propagation and for super-shear speeds. It can easily be shown that his diagram can be reduced to a single nondimensional number κ .

4.2.2 Sustained Rupture Propagation

To characterize the conditions for sustained rupture propagation in a heterogeneous initial stress field, we consider a very simple rectangular asperity model. It consists of a homogeneous initial stress field that contains a long asperity of width W loaded with a longitudinal shear stress T_e . The asperity is surrounded by an infinite fault plane where stress is low, only $0.1 T_u$, where as before T_u is the peak frictional stress. At time $t = 0$, rupture is initiated by forcing rupture over a circular patch of radius $R > R_c$, where R_c is computed from Eq. (19) using $\kappa = 0.6$. Depending on the values of T_e and the width W , rupture either grows along the asperity or stops very rapidly. We are again in the presence of bifurcation with a critical value. Similarly to Eq. (19), we define a nondimensional number

$$\kappa = \frac{T_e^2}{\mu T_u} \frac{W}{D_c}, \quad (22)$$

where we have replaced the relevant length scale W in the numerator. We then verified numerically that ruptures stop for low values of $\kappa < \kappa_c$ and grow indefinitely for $\kappa > \kappa_c$, where κ_c is a numerically determined bifurcation point. As shown by Madariaga and Olsen (2000), $\kappa_c = 0.7$ for sustained rupture along a rectangular asperity. This value is slightly larger than $\kappa_c = 0.6$ for rupture initiation, a logical result explained by the fact that it is easier to propagate rupture on a uniformly loaded fault than on a fault loaded along a narrow asperity. Again, for a certain value of $\kappa > 1.3\kappa_c$, rupture grows initially at very high speeds and then jumps to a speed higher than the shear-wave velocity.

Color Plate 4, part (a) shows rupture propagation along the long rectangular asperity for three values of κ . Left and right panels show simultaneous snapshots of shear stress and slip, respectively. The top row shows snapshots for $\kappa < \kappa_c$. Rupture

in this case starts near the asperity and then stops immediately. D_c is large relative to the value of W . The second row shows stress and slip rate when κ is slightly supercritical. The rupture propagates along the asperity at sub-shear speeds. As the rupture propagates, the rupture zone extends slightly outside the asperity, leaving an elongated final fault shape. Finally, the bottom row shows snapshots when κ is about 1.2 times critical. Now the rupture front is running faster than the shear wave producing a wake that spreads somewhat into the lower prestress zone. Thus we are again in the presence of a bifurcation: It is not enough to initiate a rupture, the stress field has to be high enough to maintain the continued rupture propagation.

5. Dynamic Model of a Major Earthquake: The 1992 M 7.3 Landers, California, Event

The 28 June 1992, magnitude 7.3 Landers earthquake occurred in a remotely located area of the Mojave Desert in Southern California (Figure 8), but the rupture process has been extensively studied due to its large size, proximity to the southern California metropolitan areas, and wide coverage by seismic

instruments. Several studies inverted the rupture history of this event from a combination of seismograms, geodetic and geologic data, and the overall kinematics of the seismic rupture are thought to be understood (Campillo and Archuleta, 1993; Abercrombie and Mori, 1994; Cohee and Beroza, 1994; Dreger, 1994; Wald and Heaton, 1994; Cotton and Campillo, 1995a), making the Landers earthquake an appropriate test case for dynamic modeling. The work described in this section is a summary of work by Olsen *et al.* (1997) and Peyrat *et al.* (2001).

5.1 Estimation of Initial Stress and Frictional Parameters

The fault that ruptured during the Landers earthquake can be divided into three segments: The Landers/Johnson Valley (LJV) segment to the southeast where the hypocenter was located; the Homestead Valley (HV) segment in the central part of the fault; and the Camp Rock/Emerson (CRE) segment to the northwest. For the numerical simulations, the three segments of the fault were replaced by a single 78 km long vertical fault plane extending from the surface down to 15 km depth. A free-surface boundary condition was imposed at the top of the grid.

The most important parameter required for dynamic modeling is the initial stress on the fault before rupture starts; all other observables of the seismic rupture, including the motion

FIGURE 8 Topographic map showing the surface rupture from the 1992 Landers earthquake. The fault trace is depicted by the black lines.

of the rupture front, are determined by the friction law. An initial stress field was estimated by Olsen *et al.* (1997) from the slip distribution inverted by Wald and Heaton (1994). They simply computed the stress drop from the slip distribution; the initial stress was the sum of a stress baseline of 5 MPa plus the stress drop reversed in sign. The method of computing the initial stress field is similar to that introduced by Mikumo and Miyatake (1995) and used by Beroza and Mikumo (1996) and Bouchon (1997) to study the stress field of several earthquakes in California.

The simple slip weakening friction law discussed in an earlier section was used in the dynamic simulations. Slip was assumed to occur only along the long dimension of the fault, and it was found that a constant yield stress level of 12 MPa and $D_c = 0.80$ m produced a total rupture time and final slip distribution in agreement with kinematic inversion results. Before the simulation the initial stress $\mathbf{T}^0$ on the fault was constrained to values just below the specified yield level (12 MPa) in order to prevent rupture starting from several locations. The same regional 1D model of velocities and densities as in Wald and Heaton (1994) was used in the numerical simulation. Rupture was forced to initiate by lowering the yield stress in a small patch of radius 1 km inside a high-stress region near the hypocenter toward the southern end of the LJV fault strand, as inferred from the kinematic results.

5.2 Rupture Propagation in a Heterogeneous Stress Field

Olsen *et al.* (1997) presented the first study on spontaneous rupture propagation in a realistic heterogeneous stress field on the Landers fault. They found that the rupture propagated along a complex path, predominantly breaking patches of high stress and almost completely avoiding areas of low or negative stress. The general rupture pulse resembles the fast, almost instantaneous self-healing phase with a finite slip duration proposed by Heaton (1990) for large earthquakes. However, the healing of the pulse was controlled by the local length scale of stress distribution, and not by slip rate weakening or fault width. Olsen *et al.* (1997) also succeeded in reproducing the main features of the low-frequency ground motion for amplitude and waveform at four strong-motion stations. These results suggested that considerable new information could be obtained about rupture dynamics through studies of spontaneous rupture propagation in estimates of the heterogeneous stress field for well-recorded large earthquakes.

5.3 Inversion of Strong Motion Data

In a recent dynamic inversion, Peyrat *et al.* (2001) used the stress field constructed by Olsen *et al.* (1997) to start the inversion of accelerograms for the initial stress field. Peyrat *et al.* used the strong motion data recorded in the vicinity of the Landers fault to invert for the details of the rupture process

by trial and error. For every initial stress distribution they computed the spontaneous rupture process, starting from the same initial asperity at the southwestern end of the fault. During the iterations, the geometry of the fault and the slip weakening friction law did not change, so that $T_u = 12$ MPa and $D_c = 0.8$ m for all the models they tested.

The preferred initial stress from the Peyrat *et al.* (2001) study is shown in Color Plate 4(b), and Color Plate 3(c) compares the rupture propagation for the dynamic model to that for the kinematic model computed by Wald and Heaton. In the case of the dynamic model, soon after initiation rupture propagates slowly downward. After 7 sec it appears that the rupture almost dies but, soon after, it suddenly accelerates upward. It again slows down at 11 sec before jumping to a northern part of the fault and continuing onward. Finally, the rupture finished on the shallow northwest part of the fault after about 21 sec, in agreement with the kinematic inversion. The rupture shows a confined band of slip propagating unilaterally toward the northwest along the fault, as pointed out by Heaton (1990). The finite width of the fault promotes the formation of a pulse by confining the rupture laterally, preventing the development of a cracklike rupture. The main differences between the kinematic and dynamic models occur within the first 10 sec of propagation. The slip rate peak at 5–6 sec for the kinematic model appears later (at 9 sec) for the dynamic model. Nevertheless, the main part of the rupture history (13–17 sec) is very similar for both models. Part (c) of Color Plate 4 shows the final slip distribution on the fault. The dynamic rupture model reproduces a smooth version of the slip pattern used to compute the initial stress distribution.

Accelerograms at the recording stations were computed using a frequency–wavenumber summation method that is more economical than using finite differences to propagate waves from the source to the stations. Figure 9 shows a comparison of the synthetic seismograms generated by the best model of Peyrat *et al.* (2001). Both synthetic and observed seismograms are low-pass filtered to frequencies below 0.5 Hz. The main features of the low-frequency ground motion for amplitude and waveform are reproduced by the synthetic seismograms for the relatively stronger ground motion recorded in the forward rupture direction. The fits for the back-azimuth stations were not as good because the effects of propagation and fault geometry are enhanced at these stations.

The dynamic rupture model of the Landers earthquake is controlled by several friction parameters that are not measured but that may eventually be determined by inversion of seismic and geodetic data. For instance, the rupture speed and healing of the fault are critically determined by the level of the yield stress and the slip weakening distance. If the slip weakening distance is chosen less than about 0.6–0.8 m, the rupture duration and therefore rise times are much shorter than those obtained from kinematic inversion (Campillo and Archuleta, 1993; Abercrombie and Mori, 1994; Cohee and Beroza, 1994; Dreger, 1994; Wald and Heaton, 1994; Cotton and Campillo, 1995),

FIGURE 9 Comparison between observed ground displacements (thick traces) and those obtained for the preferred dynamic rupture model of the Landers 1992 earthquake (thin traces). For each station the upper trace is the east–west component of displacement and the bottom trace is the north–south component. The time window is 80 sec, and the amplitude scale is the same for each station.

while larger values produce a rupture resistance that prevents rupture from propagating at all. While the rupture duration and rise times are strongly related to the slip weakening distance, the final slip distribution remains practically unchanged for slip weakening distances that allow rupture propagation.

In addition to the asperity model, Peyrat *et al.* also inverted a barrier model with constant initial stress and variable yield stress. Although the dynamic parameters for the two models are inherently different, they both generate radiation in agreement with strong-motion data. Thus we have showed that the solution of the dynamic problem is non-unique.

6. Earthquake Heterogeneity and Dynamic Radiation

Initial models of dynamic rupture propagation (e.g., Burridge and Knopoff, 1967; Andrews, 1976a,b) studied the frictional instability of a uniformly loaded fault. Very rapidly it was realized that heterogeneity was an essential ingredient of seismic ruptures and that the simple uniformly loaded faults could not explain many significant features of seismic radiation. Two models of heterogeneity were proposed in the late 1970s, the “asperity” model of Kanamori and Stewart (1978), based on a study of the Guatemalan earthquake of 1976, and the barrier model of Das and Aki (1977b) and Aki (1979). The differences between the two models were discussed in some detail by Madariaga (1979), who pointed out that it would be very difficult to distinguish between these two models from purely seismic observations. This remains true today. In the asperity model, it is assumed that the initial stress field is very heterogeneous because previous events have left the fault in a very complex state of stress. In the barrier model, heterogeneity is produced by rapid changes in rupture resistance so that an earthquake would leave certain patches of the fault (barriers) unbroken. It was quickly realized that barriers and asperities were necessary in order to maintain a certain degree of heterogeneity on the fault plane that could explain the properties of high-frequency seismic wave radiation, and to leave highly stressed patches that would be the sites of aftershocks and future earthquakes. Andrews (1980, 1981) went much further and suggested that this heterogeneity was absolutely necessary, otherwise earthquakes would become dominated by very low frequencies and could not produce observed accelerograms. Heterogeneity was studied in many ways by a number of authors during the early 1980s (e.g., Day, 1982b; Das, 1980; Kostrov and Das, 1989).

6.1 Generation of Cracks Versus Self-Healing Pulses

Heaton (1990) noticed that the instantaneous rupture area for large earthquakes is seldom larger than about 10% of the total fault area, so that seismic ruptures look more like a patch

propagating across the fault compared to Kostrov’s (1964) model of a self-similar shear crack. Heaton explained the pulselike behavior with a self-healing mechanism due to velocity weakening friction. Similar pulselike behavior has been reported from modeling a rectangular fault with a large aspect ratio due to stopping phases from the edges of the fault (Day, 1982a; Cotton and Campillo, 1995a). More recently, Beroza and Mikumo (1996), Ide and Takeo (1997), and Day *et al.* (1998) have shown that short rupture pulses may also be generated by the so-called geometrical constraint in which these short durations may simply reflect the stress heterogeneity on the fault. If stress is concentrated in small areas of the fault, the rupture process will reflect this heterogeneity and produce rupture pulses controlled by the size of these stress asperities.

Zheng and Rice (1998) characterized the conditions for generation of self-healing pulses in terms of the steady-state strength relative to the background stress in a velocity-weakening regime. They found that pulselike rupture occurs only for rather restrictive conditions of rate dependence. They furthermore suggested that the reason why most earthquakes fail to grow to a large size may be that the crustal stresses are too low on average to allow cracklike modes and continued rupture. In other words, most earthquakes fail to maintain rupture propagation because the driving stresses are too low and stop before producing a significant moment release.

6.2 Memory of Earthquake Rupture: Recurrent Events on a Fault

In this chapter we have concentrated our attention on the study of a single event without concern about earthquake recurrence or earthquake distributions. One of the main results obtained by Carlson and Langer (1989) is that for certain friction laws stress heterogeneity will be self-sustained, i.e., every event initiates in a complex state and leaves the fault loaded with a complex stress distribution. Cochard and Madariaga (1996) showed that this mechanism could also occur on two-dimensional shear faults but for a limited set of rate dependent friction laws. Only if healing were fast enough could heterogeneity develop spontaneously. The mechanism studied by Cochard and Madariaga (1996) produced heterogeneity but could not explain the Gutenberg–Richter distribution of events as a function of moment (or moment magnitude).

Nielsen *et al.* (2000) found that recurrent ruptures for a single planar fault with aspect ratio close to 1 and sufficiently low rupture resistance tended to produce a periodic cycle, always breaking the entire fault. However, if the dimension of the fault was increased with the same aspect ratio and friction, the regime became more complex and periodicity was lost. In the case of a long and narrow fault, i.e., $L/W > 10$, the pulse width $l_p \approx W$ was smaller than the maximum fault length L , and a degree of complexity was observed. Indeed, after a transient regime affected by the initial conditions, the fault settled into a recurrence pattern in which no rupture would reach the

entire length of the fault, and a wide spectrum of event sizes was produced as opposed to the periodic cycle of fault-wide events observed for faults with aspect ratio close to 1. In other words, the recurrent earthquakes on the fault would generate an inherent complexity of the stress field that completely controlled the rupture conditions for the following events.

6.3 Signature of Friction in Radiated Waves

Is it possible directly to retrieve information about friction from strong motion data? To answer this important question we need to know how (or whether) the friction manifests a signature in the radiated wave field from earthquake rupture. Ide and Takeo (1997) estimated a depth-varying slip weakening distance of 1 m near the surface and 0.5 m at depth for the 1995 Kobe earthquake using inverse techniques. Olsen *et al.* (1997) found that a slip weakening distance of 0.8 m and a yield stress of 12 MPa generated rupture durations and seismograms in good agreement with kinematic inversion results and data, respectively, for the 1992 Landers earthquake. On the other hand, Guatteri and Spudich (1998b) concluded that there is a strong trade-off between peak stress and slip weakening distances. Actually, Peyrat *et al.* (2001) found that the energy release rate $G \simeq T_u D_c$, a product of the peak stress and the slip weakening distance, is all that can be retrieved from seismic data.

If indeed the signature of friction is detectable in strong-motion data, the retrieval of such information will be possible only when data are available in sufficient quality and quantity. In this case, an estimate of friction using inverse methods may be feasible. We expect that this will be an important topic of future research.

7. Conclusions

Thanks to improvements in speed and memory capacity of parallel computers it is no longer a problem to model the propagation of seismic ruptures along a fault, or a fault system, embedded in an elastic 3D medium. The enhanced computational power can be used to improve classical models in order to determine the grid size necessary to do reproducible and stable earthquake simulations. We show that the conditions are that the slip-weakening zone near the rupture front must be sampled by at least six grid points. This is clearly a limiting condition, but it is already possible to model earthquakes of magnitudes from 6 to 7.5 without unsurmountable problems.

Recent inversions of earthquake slip distributions using kinematic source models have found that very complex source distributions require an extensive reappraisal of classical source models that were mostly based on Kostrov's model of a self-similar circular crack. Ruptures on a fault with a very heterogeneous load follow very tortuous rupture paths. While on the average the rupture propagates at a sub-shear speed

from one end of the fault to the other, the rupture front may wander in any direction, following the areas of strong stress concentration and avoiding those areas with low stress or high rupture resistance. If this view of earthquake rupture is confirmed by future observations (we believe it will be) then many current arguments about earthquake complexity, narrow rupture pulses, earthquake distributions, etc., will be solved and we may concentrate on the interesting problem of determining which features of friction control stress complexity on the fault under all circumstances.

Acknowledgments

We thank Takeshi Mikumo and Joe Andrews for very detailed and helpful reviews. R. Madariaga's work was supported by CNRS (Centre National de la Recherche Scientifique) under contract 99PNRN13AS of the PNRN program. K.B. Olsen's work was supported by the Southern California Earthquake Center (SCEC). SCEC is funded by NSF Cooperative Agreement EAR-8920136 and USGS Cooperative Agreements 14-08-0001-A0899 and 1434-HQ-97AG01718. This is ICS contribution 378-116EQ and SCEC contribution number 539.

Scattering and Attenuation of Seismic Waves in the Lithosphere

Haruo Sato

Ru-Shan Wu

University of California, Santa Cruz, California, USA

1. Attenuation of Seismic Waves

The scattering and attenuation of high-frequency seismic waves are important characteristics to be quantified and with which to physically characterize the Earth medium. We first compile measurements of attenuation of seismic waves, and discuss physical mechanisms of attenuation in the lithosphere: Intrinsic absorption and scattering loss due to distributed heterogeneities. As a model of attenuation, we introduce an approach for calculating the amount of scattering loss in a manner consistent with conventional seismological attenuation measurements.

1.1 Observed Attenuation of P- and S-Waves

The observed seismic wave amplitudes usually decay exponentially with increasing travel distance after correction for geometrical spreading, and decay rates are proportional to Q^{-1} , which characterizes the attenuation. For outgoing spherical S waves of frequency f in a medium with uniform velocity, the spectral amplitude at a travel distance r varies as

$$u^{\text{direct}}(r; f) \propto \frac{e^{-\pi r f Q_s^{-1} / \beta_0}}{r}$$

where β_0 is the S -wave velocity. We compile reported values of Q_s^{-1} and Q_p^{-1} for the lithosphere in Figures 1a and 1b,

FIGURE 1 (a) Reported values of Q_s^{-1} for the lithosphere: surface wave analysis, 1–2; coda normalization method and multiple lapse time window analysis, 3–12; spectral decay analysis, 11–26. (b) Reported values of Q_p^{-1} for the lithosphere: surface wave analysis, 1; spectral decay analysis, 2–8; extended coda normalization method, 9–10. Detailed references are given by Sato and Fehler (1998). (Reprinted from Sato and Fehler (1998) with permission from Springer-Verlag.)

respectively. Anderson and Hart (1978) proposed $Q_S^{-1} \approx 0.002$, $Q_P^{-1} \approx 0.0009$, and ratio $Q_P^{-1}/Q_S^{-1} \approx 0.5$ for frequencies <0.05 Hz for depths <45 km. Analyzing teleseismic P and S waves, Taylor *et al.* (1986) found that Q_S^{-1} was larger in the Basin and Range Province than in the North-American Shield. Analyzing records of microearthquakes in Kanto, Japan using the coda normalization method (see Section 2.4), Aki (1980) found that Q_S^{-1} decreases with increasing frequency as a power law $Q_S^{-1} \propto f^{-(0.6-0.8)}$ for 1–25 Hz. Kinoshita (1994) reported a decrease in Q_S^{-1} with decreasing frequency for frequencies less than about 0.8 Hz (curve 16 in Fig. 1a) in southern Kanto, Japan. Yoshimoto *et al.* (1993) estimated $Q_S^{-1} \approx 0.012f^{-0.73}$ and $Q_P^{-1} \approx 0.031f^{-0.5}$ for 1–32 Hz in Kanto, Japan for depth <100 km, and the resultant ratio Q_P^{-1}/Q_S^{-1} is larger than 1. Yoshimoto *et al.* (1998) found rather strong attenuation in the shallow crust, $Q_S^{-1} \approx 0.0034f^{-0.12}$ and $Q_P^{-1} \approx 0.052f^{-0.66}$ for 25–102 Hz. Carpenter and Sanford (1985) reported $Q_P^{-1}/Q_S^{-1} \approx 1.5$ for 3–30 Hz in the upper crust of the central Rio Grande Rift.

We may summarize the observed characteristics as follows: Q_S^{-1} is of the order of 10^{-2} at 1 Hz and decreases to the order of 10^{-3} at 20 Hz. It seems reasonable to write the frequency dependence of attenuation in the form of a power law as $Q_S^{-1} \propto f^{-n}$ for frequencies higher than 1 Hz, where the power n ranges from 0.5 to 1. The frequency dependence at 0.1–1 Hz remains poorly understood because seismic measurements in this band are difficult to make. Results in Figure 1b show that Q_P^{-1} also decreases with increasing frequency for frequencies higher than 1 Hz. For frequencies lower than 0.05 Hz, the ratio Q_P^{-1}/Q_S^{-1} has been taken to be a constant less than 1. Many have assumed that the ratio for higher frequencies is the same as for low frequencies. However, recent observations have clearly shown that the ratio Q_P^{-1}/Q_S^{-1} ranges between 1 and 2 for frequencies higher than 1 Hz (Yoshimoto *et al.*, 1993).

There have been many attempts to derive attenuation tomogram images from the spectral decay analysis of recorded body waves (Clawson *et al.*, 1989; Al-Shukri and Mitchell, 1990; Scherbaum and Wyss, 1990; Ponko and Sanders, 1994). It is important to overcome the trade-off between the frequency dependences of source spectra and Q^{-1} , and to remove site amplification factors near the recording station for imaging the attenuation structure: Some supposed the ω^2 model for source spectra and frequency-independent Q^{-1} in the analyses.

Seismic attenuation is usually considered to be a combination of two mechanisms—scattering loss and intrinsic absorption. Measurements of attenuation of direct seismic waves give values for total attenuation. Scattering redistributes wave energy within the medium. Conversely, intrinsic absorption refers to the conversion of vibration energy into heat. Wu (1985) introduced the concept of seismic albedo B_0 as the ratio of scattering loss to total attenuation.

1.2 Intrinsic Absorption

Several review papers discuss proposed mechanisms for intrinsic absorption that lead to frequency-independent Q_P^{-1} and Q_S^{-1} (Knopoff, 1964; Jackson and Anderson, 1970; Mavko and Nur, 1979; Dziewonski, 1979). For seismic waves to remain causal in the presence of attenuation, the relationship between frequency-dependent Q^{-1} and velocity dispersion was discussed by Liu *et al.* (1976).

Many proposed mechanisms are based on the observation that crustal rocks have microscopic cracks and pores, which may contain fluids. These features have dimensions much smaller than the wavelengths of regional seismic phases. Walsh (1966) proposed frictional sliding on dry surfaces of thin cracks as an attenuation mechanism. Nur (1971) proposed viscous dissipation in a zone of partially molten rock to explain the low-velocity/high-attenuation zone beneath the lithosphere. Even though the addition of water reduces the melting temperature of rocks, it is unlikely that melted rock exists in most regions of the lithosphere. Mavko and Nur (1979) examined the effect of partial saturation of cracks on absorption: fluid movement within cracks is enhanced by the presence of gas bubbles. O'Connell and Budiansky (1977) proposed a model in which fluid moves between closely spaced adjacent cracks. Tittmann *et al.* (1980) measured an increase of Q_S^{-1} with increasing content of volatiles in dry rocks. They found that the rapid increase was due to an interaction between adsorbed water films on the solid surface by thermally activated motion. Thermally activated processes at grain boundaries have been proposed as an absorption mechanism for the upper mantle (Anderson and Hart, 1978; Lundquist and Cormier, 1980). Spatial temperature differences induced by adiabatic compression during wave propagation will be reduced by thermal diffusion (Zener, 1948; Savage, 1966a), which removes vibrational energy from the wave field. Grain-sized heterogeneities in a rock increase the amount of predicted absorption by this mechanism, which is termed the thermoelastic effect. Savage (1966b) investigated thermoelasticity caused by stress concentrations induced by the presence of cracks.

Most of the mechanisms discussed above can predict Q_S^{-1} having values in the range of 10^{-3} ; however, the importance of various mechanisms varies with depth, temperature, fracture content, fracture aspect ratios, pressure, and the presence of fluids. Aki (1980) discussed the relation between physical dimensions and the observed and partially conjectured frequency-dependence of Q_S^{-1} with a peak on the order of 0.01 around 0.5 Hz. He preferred thermoelasticity as the most viable model at lithospheric temperatures since the required scales for rock grains and cracks along with the amount of attenuation are in closest agreement with observations.

1.3 Scattering Loss

Scattering due to heterogeneities distributed in the Earth also causes a decrease in amplitude with travel distance (Aki, 1980),

where the characteristic frequency is determined by a characteristic spatial scale, such as the correlation length of random media or the crack length. We begin to study scattering using the scalar wave equation in inhomogeneous media. We suppose the wave velocity is written as $V(\mathbf{x}) = V_0[1 + \xi(\mathbf{x})]$, where V_0 is the background velocity and the small fractional fluctuation $\xi(\mathbf{x})$ is a homogeneous and isotropic random function of coordinate $\mathbf{x}$. We imagine an ensemble of random media $\{\xi(\mathbf{x})\}$. First, we define the autocorrelation function (ACF) $R(\mathbf{x}) \equiv \langle \xi(\mathbf{y})\xi(\mathbf{y} + \mathbf{x}) \rangle$ as a statistical measure. The spatial scale and the strength of inhomogeneity are characterized by correlation length a and the mean-square fractional fluctuation ε^2 , respectively. We divide the random medium into blocks of dimension larger than a . We imagine a scalar plane wave of angular frequency ω of unit amplitude incident upon a localized inhomogeneity. We calculate the generation of outgoing scattered waves using the Born approximation. Taking the ensemble average of the squared scattering amplitude at scattering angle ψ , we get the directional scattering coefficient, which is the scattering power per unit volume, at angular frequency ω as

$$g(\psi; \omega) = \frac{k^4}{\pi} P\left(2k \sin \frac{\psi}{2}\right) \quad (1)$$

where wavenumber $k = \omega/V_0$ and P is the power spectral density function (PSDF) of random inhomogeneity.

The fractional scattering loss of incident-wave energy per unit travel distance is the average of $g(\psi; \omega)$ over solid angle, which is the total scattering coefficient g_0 (Aki and Richards, 1980). Dividing g_0 by k , we get scattering loss

$$\begin{aligned} {}^{\text{BSc}}Q^{-1}(\omega) &\equiv \frac{g_0}{k} = \frac{1}{4\pi k} \oint g(\psi; \omega) 2\pi \sin \psi d\psi \\ &= \frac{k^3}{2\pi} \int_0^\pi P\left(2k \sin \frac{\psi}{2}\right) \sin \psi d\psi \end{aligned} \quad (2)$$

In the case of exponential ACF $R(\mathbf{x}) = \varepsilon^2 e^{-r/a}$, with PSDF $P(\mathbf{m}) = 8\pi\varepsilon^2 a^3/(1 + a^2 m^2)^2$, the asymptotic behavior is ${}^{\text{BSc}}Q^{-1} \approx 2\varepsilon^2 ak$, for $ak \gg 1$. As plotted by a dashed curve in Figure 2, Eq. (2) predicts attenuation larger than ε^2 for large ak even if ε^2 is small. The large scattering loss here predicted for high frequencies is caused by strong forward scattering in a cone around the forward direction, $\psi < 1/ak$. There is a disagreement between ${}^{\text{BSc}}Q^{-1}$ obtained from direct application of the Born approximation and observed Q_S^{-1} , which decreases with increasing frequency for high frequencies (see Fig. 1a).

Wu (1982) proposed a method for calculating the scattering loss by specifying a lower bound of scattering angle $\psi_C = 90^\circ$ in Eq. (2) by arguing that this accounts only for the back-scattered energy, which is lost:

$${}^{\text{CSc}}Q^{-1}(\omega) = \frac{k^3}{2\pi} \int_{\psi_C}^\pi P\left(2k \sin \frac{\psi}{2}\right) \sin \psi d\psi \quad (3)$$

FIGURE 2 Scattering attenuation versus ak for scalar waves: dashed curve, the ordinary Born approximation; solid curves, the corrected Born approximation, where $k = \omega/V_0$. $\psi_C = 90^\circ$ by Wu (1982) and $\psi_C = 29^\circ$ by Sato (1982).

Sato (1982) suggested that the strong increase in attenuation predicted by the Born approximation for high frequencies is due to the travel time (phase) fluctuation caused by velocity fluctuation. He proposed a method for calculating the scattering loss after subtracting the travel time fluctuation caused by velocity fluctuation of which the wavelengths are larger than twice the wavelength of incident waves. This procedure ignores scattering loss for angles smaller than $\psi_C \approx 29^\circ$ in Eq. (3). For an exponential ACF, corrected scattering loss ${}^{\text{CSc}}Q^{-1}$ has a peak of the order of ε^2 at $ak \approx 1$, and becomes ${}^{\text{CSc}}Q^{-1}(\omega) \propto \varepsilon^2/ak$, for $ak \gg 1$. Solid curves in Figure 2 show the scattering loss given by Eq. (3) against ak . Such a frequency dependence well explains the observed frequency dependence of attenuation as shown in Figure 1. Extending the above idea to elastic vector waves and fitting the predicted scattering loss curve to observed Q_S^{-1} , Sato (1984) estimated $\varepsilon^2 = 0.01$ and $a = 2$ km for the lithosphere. The choice of ψ_C was numerically examined by several investigators (Frankel and Clayton, 1986; Roth and Korn, 1993; Fang and Müller, 1996).

There have been many studies of scattering by distributed cracks and cavities (Varadan *et al.*, 1978; Kikuchi, 1981; Matsunami, 1990; Benites *et al.*, 1992, 1997; Kawahara and Yamashita, 1992). Scattering by cracks gives a peak in Q^{-1} when the wavelength is of the same order as the dimension of the crack; however, it is difficult to imagine open cracks having dimensions large enough to be comparable to regional seismic wavelengths deep in the Earth.

2. Seismogram Envelopes of Local Earthquakes

The appearance of coda waves in seismograms is one of the most prominent observations supporting the existence of small-scale random heterogeneities in the Earth (Aki, 1969).

We will now discuss characteristics of observed coda. Then we will introduce the radiative transfer theory, which can account for the effects of multiple scattering and model observed coda characteristics. We compile measurements of total scattering coefficient and coda attenuation, which characterize coda excitation and coda amplitude decay, respectively. We will then discuss the coda normalization method, which is widely used for the estimation of attenuation per travel distance, site amplification factors, and source spectra on the basis of the spatially uniform distribution of coda energy at a long lapse time. Finally, we will present the multiple lapse time window analysis method that has been developed for the measurement of scattering loss and intrinsic absorption based on the solution of the radiative transfer theory.

2.1 Coda Characteristics

We show seismograms of a typical local earthquake in Figure 3: the direct S wave is followed by complex wave trains, which are called “ S -coda” or simply “coda.” Clear S -coda waves have been identified on seismograms recorded at the bottom of deep boreholes (Sato, 1978; Leary and Abercrombie, 1994). The f - k analysis of array seismic data shows that S -coda is composed of many wavelets arriving from various directions. Recorded waveforms show a large variation in amplitude near the direct S arrival; however, the variation decreases as lapse time increases. S -coda waves have a common envelope shape at most stations near the epicenter after about twice the S wave travel time (Rautian and Khalturin, 1978). The logarithm of the trace duration of a local seismogram is generally proportional to earthquake magnitude. Trace duration has been used for the quick determination of earthquake magnitudes in many regions of the world (Tsumura, 1967).

2.2 Radiative Transfer Theory

Wu (1985) and Shang and Gao (1988) first introduced the radiative transfer theory into seismology; later Zeng *et al.* (1991) formulated the time-dependent multiple scattering process in 3D. Here, we introduce a theory for multiple isotropic scattering processes for a point shear-dislocation source (Sato *et al.*, 1997). We consider a nonabsorbing 3D scattering medium with background propagation velocity V_0 , in which pointlike isotropic scatterers of cross section σ_0 are randomly and homogeneously distributed with density n , where the total scattering coefficient $g_0 \equiv n\sigma_0$. We assume an impulsive source located at the origin of energy W with radiation pattern $\Xi(\theta, \phi)$ (see Fig. 4a) at time zero. The scattering process is written as

$$E(\mathbf{x}, t) = W\Xi(\theta, \phi)G_E(\mathbf{x}, t) + g_0V_0 \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} G_E(\mathbf{x} - \mathbf{x}', t - t')E(\mathbf{x}', t') d\mathbf{x}' dt' \quad (4)$$

FIGURE 3 Horizontal component velocity seismograms of a crustal earthquake of $M_L = 4.6$ in Japan. Seismograms are arranged from bottom to top by increasing distance from the earthquake epicenter. The direct S wave is followed by S -coda waves. (Courtesy of K. Obara.)

where the convolution integral means the propagation of energy from the last scattering point to the receiver. The first term is for the direct propagation, where

$$G_E(\mathbf{x}, t) = \frac{1}{4\pi V_0 r^2} H(t) \delta\left(t - \frac{r}{V_0}\right) e^{-g_0 V_0 t} \quad (5)$$

We can analytically solve Eqs. (4)–(5) by using the Fourier–Laplace transform in space–time, and a spherical harmonics

FIGURE 4 (a) Geometry of the multiple scattering process for a point-shear dislocation source, where the lobes show the radiation pattern of the S -wave energy. (b) Temporal change in the normalized energy density at $r = 1/g_0$ in different directions from a point shear-dislocation source. The broken curve corresponds to the spherical source radiation. (Reprinted from Sato *et al.* (1997) with permission from Elsevier Science.)

expansion in angle. For the case of spherical source radiation, $\Xi = 1$, Zeng *et al.* (1991) obtained

$$\begin{aligned}
 E(\mathbf{x}, t) = & \frac{W}{4\pi V_0 r^2} \delta\left(t - \frac{r}{V_0}\right) e^{-g_0 V_0 t} H(t) \\
 & + \frac{W g_0 e^{-g_0 V_0 t}}{4\pi r^2} \frac{r}{V_0 t} \ln\left[\frac{r + V_0 t}{r - V_0 t}\right] H\left(t - \frac{r}{V_0}\right) \\
 & + W g_0^2 V_0^2 \frac{1}{(2\pi)^2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} d\omega dk e^{-i\omega t - ikr} \\
 & \times \frac{ik}{2\pi r} \frac{\bar{G}_{E0}(-k, -i\omega)^3}{1 - g_0 V_0 \bar{G}_{E0}(-k, -i\omega)}
 \end{aligned} \quad (6)$$

where $\bar{G}_{E0}(k, s) = (1/kV_0) \tan^{-1} [kV_0/(s + g_0 V_0)]$. The second term on the right hand side is the single scattering term (Kopnichen, 1975; Sato, 1977), which decreases according to the inverse square of lapse time at large lapse time as $W g_0 / 2\pi V_0^2 t^2$ (Aki and Chouet, 1975).

We show temporal variations of normalized energy density ($\bar{E} = E/W g_0^3$) against normalized lapse time ($\bar{t} = g_0 V_0 t$), at distance of one mean free path $r = g_0^{-1}$ for a point shear-dislocation source by solid curves (Sato *et al.*, 1997) in Figure 4b. The energy density faithfully reflects the source radiation pattern near the direct arrival; however, the azimuthal dependence diminishes with increasing lapse time. Each solid curve asymptotically converges to a broken curve for spherical source radiation. This simulation agrees qualitatively with the observed radiation pattern independence of coda amplitudes at long lapse time.

It should be mentioned that the energy flux model (Frankel and Wennerberg, 1987) and the use of Monte Carlo methods (Hoshiba, 1991; Gusev and Abubakirov, 1996) for envelope synthesis played important roles in the coda study.

2.3 Coda Attenuation and Scattering Coefficient

The coda energy density in a frequency band having central frequency f is the sum of the medium mass density times average square of particle velocity of S -coda around lapse time t , $\bar{u}_i^{S\text{-coda}}(t, f)$ as

$$E^{S\text{-coda}}(t, f) \approx \sum_{i=1}^3 \rho_0 \bar{u}_i^{S\text{-coda}}(t, f)^2$$

where ρ_0 is the mass density. For practical analysis, we need to introduce an empirical parameter, known as coda attenuation Q_C^{-1} . In the case of single scattering model, the coda decay curve is given by

$$E^{S\text{-coda}}(t, f) \approx \frac{W g_0}{2\pi V_0^2 t^2} e^{-Q_C^{-1}(f) 2\pi f t} \quad \text{for} \quad t \gg \frac{2r}{V_0} \quad (7)$$

Figure 5a summarizes reported coda attenuation. In general, Q_C^{-1} is about 10^{-2} at 1 Hz and decreases to about 10^{-3} at 20 Hz. The frequency dependence within a region can be written as $Q_C^{-1} \propto f^{-n}$ for $f > 1$ Hz, where $n \sim 0.5$ –1. Regional differences of Q_C^{-1} were extensively studied in relation to seismotectonic settings (Singh and Herrmann, 1983; Jin and Aki, 1988;

FIGURE 5 (a) Coda attenuation Q_C^{-1} against frequency for various regions. (b) Total scattering coefficient g_0 for SS scattering versus frequency, from regional measurements made throughout the world: results obtained using the single-scattering model are labeled 1–5 (plots include backscattering coefficient g_π); results based on the multiple lapse time window analysis (isotropic scattering is assumed) are labeled 6–8. Detailed references are given by Sato and Fehler (1998). (Reprinted from Sato and Fehler (1998) with permission from Springer-Verlag.)

Matsumoto and Hasegawa, 1989). We may say that Q_C^{-1} is smaller in tectonically stable areas and larger in active areas. Comparing the observed coda energy density with that predicted from theoretical coda models, we can estimate total scattering coefficient g_0 for S -to- S scattering. Figure 5b shows reported g_0 , which is of the order of 10^{-2} km^{-1} for frequencies 1–30 Hz, and each measurement has an error of about factor 2. Nishigami (1991) and later Revenaugh (1995) inverted for the spatial distribution of scattering coefficient from the analysis of S - and P -coda amplitude residuals from the average coda decay. There have been various attempts to map coda attenuation in various scales (O'Doherty *et al.*, 1997; Mitchell *et al.*, 1997).

Seismic coda monitoring could provide information about the temporal change in fractures and attenuation caused by changes in tectonic stress during the earthquake cycle (Chouet, 1979). Jin and Aki (1986) reported a change in Q_C^{-1} associated with the occurrence of the Tangshan earthquake. Fehler *et al.* (1988) found differences in Q_C^{-1} before and after an eruption of Mt. St. Helens volcano. There have been many studies that indicate a correlation between temporal change in coda characteristics and the occurrence of large earthquakes. However, there have been criticisms, for example, concerning the possible influences of using different lapse times to establish the temporal change in coda characteristics and the effects of differing focal mechanisms and earthquake locations (Sato, 1988; Ellsworth, 1991; Frankel, 1991). Got *et al.* (1990) proposed the use of earthquake doublets. Recent measurements try to reflect those criticisms (Aster *et al.*, 1996). Analyzing short-period seismograms recorded at Riverside, California, between 1933 and 1987, Jin and Aki (1989) reported a temporal variability in Q_C^{-1} and a positive correlation with the seismic b -value. Gusev (1995) summarized coda observations made between 1967 and 1992 in Kamchatka by plotting coda magnitude residuals, and reported two prominent anomalies.

2.4 Coda Normalization Method

Coda waves provide a reliable way to isolate and quantify seismic propagation effects. Based on the single scattering model, we may write the average coda amplitude at a long lapse time t_c from the origin time at central frequency f as a product of the source, propagation, and site amplification as

$$\dot{u}^{S\text{-coda}}(t_c; f) \propto \sqrt{g_0(f)W(f)N^S(f)} \frac{e^{-Q_C^{-1}\pi f t_c}}{t_c}$$

where $N^S(f)$ is the site amplification factor, and $W(f)$ is the S -wave source energy. We suppose that $g_0(f)$ is constant in a region. The direct S -wave amplitude is written as

$$\dot{u}^{S\text{direct}}(r; f) \propto \sqrt{W(f)N^S(f)} \frac{e^{-Q_S^{-1}\pi f r/\beta_0}}{r}$$

where r is the hypocentral distance. Aki (1980) proposed a correction for source size and site amplification by normalizing direct S -wave amplitude by S -coda amplitude. Taking the logarithm of the ratio of the product of r and the direct S -wave amplitude to the averaged coda amplitude, where the common site amplification and source terms cancel, we get

$$\ln \left[\frac{r \dot{u}^{S\text{direct}}(r; f)}{\dot{u}^{S\text{-coda}}(t_c; f)} \right] = - \left(Q_S^{-1}(f) \frac{\pi f}{\beta_0} \right) r + \text{Const.} \quad (8)$$

We may smooth out the radiation pattern differences when the measurements are made over a large enough number of earthquakes. Plotting the LHS of Eq. (8) against r , the gradient gives the attenuation per travel distance. Aki (1980) first used this method for the estimation of Q_S^{-1} in Japan. Later, Yoshimoto *et al.* (1993) extended this method to measure Q_P^{-1} .

The ratio of coda amplitudes at different sites gives the relative site amplification factor since the source factor is common. Tsujiura (1978) found that estimates of site effects made using coda are similar to those obtained from direct wave measurements. He also found less variability in site effect measurements made for a single site using coda waves from various sources than from direct waves for the same sources. The ratio of coda amplitudes of different earthquakes at a single station gives the relative source radiation, since the site factor is common. These methods have been widely used around the world (Biswas and Aki, 1984; Dewberry and Crosson, 1995; Hartse *et al.*, 1995; Phillips and Aki, 1986).

2.5 Multiple Lapse Time Window Analysis

For the determination of seismic albedo, B_0 , Fehler *et al.* (1992) and Hoshihara *et al.* (1991) developed a method based on two observations. (1) The early portion of an S -wave seismogram is dominated by the direct S wave whose amplitude change with distance is controlled by the total attenuation of the media; (2) S -coda level is composed entirely of scattered S waves whose amplitudes are controlled by the total scattering coefficient. Their method is based on the radiative transfer theory, in which scattering is assumed to be isotropic and radiation is spherically symmetric. They evaluate the integrated energy density as a function of source–receiver distance. Fehler *et al.* (1992) analyzed seismograms of local earthquakes in Kanto–Tokai, Japan in three frequency bands. Figure 6 shows the energy density integrated over three time windows for the 4–8 Hz band. The running means of the data over 15 km windows are plotted against distance using thin lines, and the

FIGURE 6 Normalized integrated energy density with geometrical spreading correction versus hypocentral distance in the Kanto–Tokai region, Japan, relative to the value at a hard rock borehole site for vertical component data. Average of data and best-fit theoretical curves are shown by thin lines and broad curves, respectively for the 4–8 Hz band. (Reprinted from Fehler *et al.* (1992) with permission from Blackwell Science.)

broad lines show the best fit to the observed data from the theory. Later, Hoshihara (1993) proposed a single-station method for developing three curves, where he used average coda power at a fixed lapse time for the source energy. Variations of the methods have been used to make simultaneous measurements of attenuation and scattering coefficient. Seismic albedo B_0 has been found to vary from 0.2 to 0.8 and Q_s^{-1} decreases with increasing frequency over the range 1–20 Hz.

2.6 Other Studies of Seismogram Envelopes

The whole seismogram reflects not only the source information but also the scattering characteristics of the Earth medium. Sato (1984) proposed to synthesize three-component seismogram envelopes by summing single scattered wave energy, where frequency-dependent nonisotropic scattering amplitudes are calculated on the basis of the Born approximation. S -coda amplitudes are large on all three components, where SS -scattering contributes significantly for a wide range of lapse times, and pseudo P - and S -phases appear even in the null direction. Later, Yoshimoto *et al.* (1997a,b) developed an envelope synthesis including the reflection at the free surface.

The conventional waveform inversion for the source process was not successful when applied to high-frequency seismograms. The appropriate approaches would be to disregard the phase information and focus instead on seismogram envelopes. Zeng *et al.* (1993) mapped the high-frequency radiation from the fault plane using seismogram envelope analysis based on geometrical ray theory. Gusev and Pavlov (1991), and Kakehi and Irikura (1996) proposed using seismogram envelopes of small aftershocks as an empirical Green function. By using a solution of the radiative transfer equation, Nakahara *et al.* (1998) proposed an inversion method to estimate the spatial distribution of high-frequency energy radiation from the fault plane. Analyzing records of the 1994 off-Sanriku earthquake, Japan, they reported that the spatial distribution of high-frequency radiation does not always coincide with the slip distribution determined from longer-period waves.

The duration of the observed S wave packet at distances longer than 100 km is much longer than the source duration and the peak amplitude is delayed after the first arrival (Sato, 1989). It was initially proposed that this envelope broadening is a propagation effect due to diffraction and forward scattering caused by slowly varying velocity structure, which was modeled by employing a stochastic treatment of the parabolic wave equation (Lee and Jokiipii, 1975a,b). Applying the theoretical prediction for the Gaussian ACF to envelop data observed at Kanto, Japan, Sato (1989), and Scherbaum and Sato (1991) estimated $\varepsilon^2/a \approx 10^{-(2.98 \sim 3.27)} \text{ km}^{-1}$. Analyzing the characteristics of seismogram envelopes from a larger region in Japan, Obara and Sato (1995) found that the random inhomogeneity in the back-arc side of the volcanic front is rich in short-wavelength components compared with

the Gaussian spectra. Gusev and Abubakirov (1997) reported a decrease of scattering coefficient with increasing depth revealed from the envelope broadening of both P and S waves in Kamchatka.

3. Spatial Coherence of Seismic Array Data

The common practice in dealing with multiscale, broadband heterogeneities in seismology is to smooth both the observed wave field and the heterogeneity model. In this way the information about small-scale heterogeneities is ignored and the obtained image can only recover the slowly varying, large-scale heterogeneities.

Stochastic methods, on the other hand, can obtain some statistical characteristics of the small-scale heterogeneities from the statistics of the wave field fluctuations. Statistical parameters of the medium include the RMS perturbation of velocity distribution, characteristic scale length, power spectrum, or correlation function of velocity perturbations. Thus, deterministic and stochastic methods are complementary to each other when exploring multiscale complex media. In the overlapping spectral band, the deterministic and stochastic methods observe the same object from different aspects and using different simplifications during the analysis process.

The study of stochastic characteristics of random media using forward-scattered waves started a few decades ago. In the earlier studies (e.g., Nikolaev, 1975; Aki, 1973; Capon, 1974; Berteussen, 1975; Berteussen *et al.*, 1975, 1977; McLaughlin and Anderson, 1987), only variance and transverse coherence functions (TCF) of phase and amplitude fluctuations were used. Limited by the amount of information contained in these coherence functions, the medium model description is restricted to a single layer of uniform, isotropic random medium. Through the use of the scattering theory of Chernov (1960), several statistical parameters, such as the RMS velocity perturbation, the average scale length, and the total thickness of the layer, were inferred from the observed data. At the end of the 1980s, Flatté and Wu (1988) introduced a new statistical

observable, the angular coherence function (AnCF), which significantly increased the statistical information in the reduced data sets, and allowed the authors to derive a simple model of a layered, multiscale random medium. More recently, Wu (1989), Wu and Flatté (1990), and Chen and Aki (1991) introduced the new joint coherence function (JCF) or joint transverse-angular coherence function (JTACF) and derived the theoretical relation between the joint coherence functions of array data and the heterogeneity spectrum (heterospectrum) of the random media. Wu and Xie (1991) conducted numerical experiments to test the performance of inverting JTACF to obtain the depth-dependent heterogeneity spectrum. The recent development in theory and methods greatly increases the amount of information in the statistical data set used and thereby significantly improves the model resolution, especially the depth resolution of the heterogeneity spectrum.

3.1 Observations of Amplitude and Phase Fluctuations and Their Coherences

As a result of wave diffraction and of focusing and defocusing effects caused by heterogeneities in a medium, wave front distortion and fluctuations of various parameters of the wave field such as amplitude, arrival time, and arrival angle may occur. Arrival time and amplitude fluctuations of waves crossing a seismic array such as NORSAR, LASA, and other local or regional arrays have been observed widely. The pattern of fluctuations may change drastically even between nearly colocated events.

3.1.1 Definitions of Various Coherence Functions

Coherence analysis is an effective method of describing statistical properties of the wave field. TCF defines the coherency (or similarity) of two transmitted wave fields as a function of horizontal separations between receivers; AnCF defines the coherency as a function of angles between incident waves. For the more general case, the JTACF gives the measure of coherency between two transmitted wave fields with different incident angles and observed at different stations (see Fig. 7).

FIGURE 7 Comparison of the data reduction geometry for TCF (transverse coherence function), AnCF (angular coherence function), and JTACF (joint transverse angular coherence function).

Compared with TCF and AnCF, JTACF changes the coherence data from a 1D to a 3D matrix (a function of station separation, dip, and azimuth angles) and therefore increases tremendously the information content of the coherence data set, providing more constraints for the determination of medium properties under the array. However, the advantage of increasing the resolving power is offset by decreasing the statistical stability to some degree. For real array data sets, the compromise between resolution and stability depends on the amount of data and angular coverage of the events. In practical array measurements the influence of array aperture on the calculation of coherence functions has to be taken into consideration (Flatté and Xie, 1992).

3.2 Theoretical Basis of Coherence Analysis and Inversion

The theory of transverse coherence of the wave field after passing through a uniform random medium has long been available in the literature (Chernov, 1960; Tatarskii, 1971; Munk and Zacharassen, 1976; Flatté *et al.*, 1979). However, the formulations for angular coherence and for joint coherence functions have only recently been derived by Wu and Flatté (1990) using the Rytov approximation and Markov approximation. Chen and Aki (1991) independently derived similar formulas using the Born approximation. The theory of the joint coherence functions includes the TCF and AnCF as special cases. In the derivations of Wu and Flatté (1990), spectral representation of random media is used and the depth dependency of the spectrum is introduced. Thus, the new theory is more general and more suitable for the multiscale, depth-dependent Earth heterogeneities.

In transmission fluctuation analysis, only the initial P arrival (direct P , PKP or $PKIKP$) of a seismogram is used. By doing this, all the backscattered and large-angle scattered waves are neglected. Therefore, the problem becomes a forward scattering or small-angle scattering problem, for which the scalar wave approximation can be used (Wu and Aki, 1985; Wu, 1989). In such scattering problems, only the wave speed perturbations affect the scattered field. Let the wave speed be $V(\mathbf{x}) = V_0[1 + \xi(\mathbf{x})]$, where V_0 is the deterministic background velocity and $\xi(\mathbf{x})$ is the random perturbation. Let U_0 be the wave field in the absence of fluctuations, and define the field perturbation Ψ by

$$U = U_0 e^{\Psi} \quad \text{and} \quad \Psi = \ln U - \ln U_0 = \ln \frac{A}{A_0} + i(\phi - \phi_0) = \nu + i\phi \quad (9)$$

Substituting the above equation into the wave equation and taking the Rytov approximation and parabolic approximation, we derive the formulas for the *joint coherence functions* (for the detailed derivation, see Wu and Flatté, 1990)

$$\begin{aligned} \langle \nu_1 \nu_2 \rangle(\mathbf{x}_T, \vec{\theta}) &= \frac{k^2}{4\pi^2} \int_0^H dz \int \int_{-\infty}^{\infty} d\mathbf{k}_T e^{i\mathbf{k}_T \cdot (\mathbf{x}_T + z\vec{\theta})} \\ &\quad \times \sin^2 \frac{k_T^2 z}{2k} P(\mathbf{k}_T, 0, z) \\ \langle \varphi_1 \varphi_2 \rangle(\mathbf{x}_T, \vec{\theta}) &= \frac{k^2}{4\pi^2} \int_0^H dz \int \int_{-\infty}^{\infty} d\mathbf{k}_T e^{i\mathbf{k}_T \cdot (\mathbf{x}_T + z\vec{\theta})} \\ &\quad \times \cos^2 \frac{k_T^2 z}{2k} P(\mathbf{k}_T, 0, z) \\ \langle \nu_1 \varphi_2 \rangle(\mathbf{x}_T, \vec{\theta}) &= \frac{k^2}{4\pi^2} \int_0^H dz \int \int_{-\infty}^{\infty} d\mathbf{k}_T e^{i\mathbf{k}_T \cdot (\mathbf{x}_T + z\vec{\theta})} \\ &\quad \times \sin \frac{k_T^2 z}{2k} \cos \frac{k_T^2 z}{2k} P(\mathbf{k}_T, 0, z) \end{aligned} \quad (10)$$

where $\mathbf{x}_T = \mathbf{x}_{T1} - \mathbf{x}_{T2}$ is the receiver separation vector (transverse separation), $\vec{\theta} = (\vec{\theta}_1 - \vec{\theta}_2)$ is the incident-angle separation vector, H is the propagation range in the random medium, here equal to the thickness of the random layer, $k_T = |\mathbf{k}_T|$ is transverse wavenumber and $P(\mathbf{k}_T, k_z, z)$ is the 3D power spectrum of the random heterogeneities $\xi(\mathbf{x})$ at depth z . Equation (10) gives the general formulas for coherence analysis. Putting $\mathbf{x}_T = 0$ and $\vec{\theta} = 0$ in the above formulas, we obtain the variances and covariance of the fluctuations (magnitudes of fluctuations). For the transverse coherence of the fluctuations, we put $\vec{\theta} = 0$ into Eq. (10). For the angular coherence between fluctuations for two incident plane waves with angular separation of $\vec{\theta}$, we put $\mathbf{x}_T = 0$. In the past, the space domain formulation of Chernov (1960) was used for fluctuation analysis. Explicit expressions were derived for the case of a Gaussian ACF by Chernov (see also Sato and Fehler, 1998). The corresponding formulas can be obtained by substituting a Gaussian PSDF into Eq. (10).

3.3 Inversion for Statistical Characteristics of Earth Heterogeneities

3.3.1 Estimations of Turbidity in the Crust and Upper Mantle

In the 1960s, Russian scientists conducted extensive investigations using the log-amplitude fluctuation of P wave first motion from explosions and earthquakes to infer the crustal and upper mantle “turbidity coefficients” at different depths (see Nikolaev, 1975). The turbidity coefficient is defined as the variance of log-amplitude fluctuations produced by a unit travel distance. The depth of heterogeneities contributing to the measured turbidity was estimated by determining the seismic ray travel paths. In these measurements, the turbidity coefficients were rather phenomenological or apparent parameters, which might have included spatial variations of site factors and the variations of intrinsic attenuation. Nikolaev (1975) concludes that the turbidity for 5 Hz P waves in the crust and upper mantle is $0.0001\text{--}0.0025 \text{ km}^{-1}$, with an error factor of about 2.

3.3.2 Uniform Random Medium Model for the Lithosphere

For the single-layer Gaussian medium model, the model parameters are the RMS velocity perturbation ε , correlation length a , and the layer thickness H . Correlation length a can be estimated from a measurement of the transverse correlation of log-amplitude and phase. The layer thickness H and the wave speed perturbation ε can be obtained from the measured variance and covariance of ν and ϕ . This single layer isotropic Gaussian medium model has been used to analyze the data at LASA (Aki, 1973; Capon, 1974; Berteussen *et al.*, 1975), NORSAR (Capon and Berteussen, 1974; Berteussen *et al.*, 1977), and the Gauribindanur seismic array (GBA) in Southern India (Berteussen *et al.*, 1977). It is found that the estimate of correlation length a is much better constrained than the layer thickness H and perturbation ε . For LASA, $a \approx 10$ –12 km, but H ranged from 60 to 120 km, with ε varying from 4 to 1.9% from different investigations.

3.3.3 Non-Gaussian Nature of the Heterogeneities

The Gaussian correlation function characterizes single-scale smoothly heterogeneous media, while real heterogeneities in the Earth are often multiscaled. Flatté and Wu (1988) showed that the exponential or Kolmogorov correlation functions fit the data much better than the Gaussian correlation function. The non-Gaussian nature of the lithospheric heterogeneities has been established also from velocity well-logging data (Sato, 1979; Wu, 1982).

3.3.4 Depth-Dependent Random Medium Model for the Crust and Upper Mantle

As many investigators have pointed out (Berteussen *et al.*, 1975; Flatté and Wu, 1988; Wu and Flatté, 1990), the use of only TCF resulted in poor determination of the random medium thickness and ambiguity in resolving the medium perturbation strength (variances) and the thickness. After introducing the AnCF, Flatté and Wu (1988) were able to invert both the TCF and AnCF for a more complex random medium model. They showed that a single-layer uniform random medium failed to explain the observed fluctuation coherences represented by both TCF and AnCF and proposed a two-layer (overlapping) random medium model for the crust and upper mantle beneath the NORSAR (see Fig. 8). Each layer has a different perturbation strength and a different power-law heterogeneity spectrum. The best model has the top layer extending to a depth of 200 km with a flat spectrum, representing the small-scale heterogeneities in the lithosphere, and the second layer located between 15 and 250 km with a k^{-4} power-law spectrum, where k is wavenumber. The latter spectrum characterizes the large-scale heterogeneities in the mantle. From the RMS travel time fluctuation (0.135 sec) and the RMS log-amplitude fluctuation (0.41 neper = 3.6 dB), the RMS P wave speed perturbation

FIGURE 8 Comparison between the data and the prediction of the two-layered power-law random medium model at NORSAR: (a) TCF; (b) AnCF. (Reprinted from Flatté and Wu (1988) with permission from the American Geophysical Union.)

for the first layer is 0.9–2.2% and for the second layer is 0.5–1.3%.

Based on the theory of general coherence analysis in random media, it is clear that TCF has no depth resolution and AnCF has only limited depth resolution that degenerates quickly with increasing depths. On the other hand, the joint coherency functions (JCF) increase tremendously the information content and provide high depth resolution. JTACFs have been calculated for the NORSAR data (Wu *et al.*, 1994) and the Southern California Seismic Network data (Liu *et al.*, 1994; Wu *et al.*, 1995), and some interesting findings were reported.

4. Numerical Modeling of Wave Propagation in Heterogeneous Media

We have presented some analytical methods for investigating wave propagation in heterogeneous media where only the

random component of heterogeneity is modeled. Generally, it is difficult to model random heterogeneities with deterministic structures using the methods discussed. In addition, for studies of wave propagation in random media, we usually model the mean response of a suite of random media whose statistical characterizations are the same. Results from such modeling are often difficult to relate to real Earth observations. We now briefly discuss numerical modeling of wave propagation in heterogeneous media.

Numerous modeling studies have been undertaken to investigate wave propagation in heterogeneous media using numerical modeling. Numerical methods can model a wide range of Earth structures. Studies using finite differences (Frankel and Clayton, 1986; Shapiro and Kneib, 1993), the boundary integral approach (Benites *et al.*, 1992, 1997), homogeneous layer solutions (Richards and Menke, 1983), and Fourier domain methods (Spivack and Uscinski, 1989; Hoshiba, 1999; Wu *et al.*, 2000) have been made. In each case, the choice of numerical method was based on the type of wave phenomenon being investigated. Boundary integral and finite difference solutions provide reliable solutions including all wave field phenomena in strongly heterogeneous media; however, both methods are computationally expensive and it is difficult to investigate a range of models. For example, finite difference solutions require that grid spacing be chosen to minimize grid dispersion. As the propagation times and frequency being modeled increase, the spatial grid size and time increment must decrease to minimize grid dispersion (Holberg, 1987). As an example, Wu *et al.* (2000) required a grid spacing of 0.02 times the dominant wavelength to reliably model propagation to distances of 35 wavelengths. Boundary integral approaches have restrictions on the number of fictitious sources required along each boundary to adequately match boundary conditions. As velocity heterogeneity or frequency increases, the number of fictitious sources increases and the resulting computational cost increases.

Since several complete descriptions of finite difference and boundary integral techniques are available (Holberg, 1987; Benites *et al.*, 1992), we will discuss a class of numerical modeling techniques that has received little attention among seismologists. The methods are powerful in that they can model wave propagation faster than can be done using finite difference or boundary integral approaches. The methods have been used extensively in seismic exploration since the introduction of an intuitive approach for seismic wave modeling known as phase shift plus interpolation (PSPI) by Gazdag and Sguazzero (1984), and the work of Stoffa *et al.* (1990), who extended a wave equation-based method that was well known in acoustics (see, e.g., Jensen *et al.*, 1994). The method of Stoffa *et al.* (1990) is called the split-step Fourier (SSF) approach; its reliability has been quantitatively investigated by Huang and Fehler (1998). Extensions of the SSF method have been presented by Wu (1994), Huang *et al.* (1999a,b), Huang and Fehler (1999), and Wu *et al.* (2000). The methods are

reliable for modeling wave propagation in the forward direction, but the effects of reverberations between scatterers are not included. The methods operate in the frequency domain and calculations are performed in the wavenumber and space domains. We will briefly introduce the SSF approach.

4.1 SSF Approach

The constant-density scalar wave equation in the frequency domain is

$$\left[\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} + \frac{\omega^2}{V(\mathbf{x}_T, z)^2} \right] U(\mathbf{x}_T, z; \omega) = 0 \quad (11)$$

where $\mathbf{x}_T \equiv (x, y)$, $U(\mathbf{x}_T, z; \omega)$ is the wave field in the frequency domain, $V(\mathbf{x}_T, z)$ is the velocity of the medium, and ω is the angular frequency. In some sense we can break the scalar wave equation into two parts, one representing downgoing waves and one representing upgoing waves. The equation for downgoing waves is

$$\frac{\partial}{\partial z} U(\mathbf{x}_T, z; \omega) = i\Lambda(\mathbf{x}_T, z; \omega) U(\mathbf{x}_T, z; \omega) \quad (12)$$

where the positive z direction is the propagation direction and the square-root operator Λ is defined by

$$\Lambda(\mathbf{x}_T, z; \omega) = \sqrt{\frac{\omega^2}{V(\mathbf{x}_T, z)^2} + \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}} \quad (13)$$

The formal split-step marching solution of the one-way wave equation is given by

$$U(\mathbf{x}_T, z_i + \Delta z; \omega) = \exp \left[i \int_{z_i}^{z_i + \Delta z} \Lambda(\mathbf{x}_T, z; \omega) dz \right] U(\mathbf{x}_T, z_i; \omega) \quad (14)$$

where we assume we know the wave field at z_i and we wish to compute the wave field at $z_i + \Delta z$. Huang and Fehler (1998) discuss how to use a small-angle approximation to evaluate the exponential of the integral in Eq. (14) to obtain

$$U(\mathbf{x}_T, z_{i+1}; \omega) = \exp \left[i\omega \left(\int_{z_i}^{z_{i+1}} \Delta s(\mathbf{x}_T, z) dz \right) \right] U_0(\mathbf{x}_T, z_{i+1}; \omega) \quad (15)$$

where the slowness heterogeneity $\Delta s \equiv 1/V(\mathbf{x}_T, z) - 1/V_0(z)$ is assumed to be small, and $U_0(\mathbf{x}_T, z_{i+1}; \omega)$ is the wave field at z_{i+1} obtained by propagation of the wave field across the interval Δz where the interval is assumed to have homogeneous velocity V_0 and

$$U_0(\mathbf{x}_T, z_{i+1}; \omega) = F_{\mathbf{k}_T}^{-1} \left\{ e^{ik_z(z_i)\Delta z} F_{\mathbf{x}_T} \{ U(\mathbf{x}_T, z_i; \omega) \} \right\} \quad (16)$$

where $k_z(z_i) = \sqrt{k_0(z_i)^2 - \mathbf{k}_T^2}$ and $k_0 = \omega/V_0(z_i)$. $F_{\mathbf{x}_T}$ and $F_{\mathbf{k}_T}^{-1}$ are 2D Fourier and inverse Fourier transforms over $\mathbf{x}_T$ and $\mathbf{k}_T$, respectively. Wave propagation is done in two steps: a free space propagation in the wavenumber domain across each depth interval using the background slowness s_0 for the interval, followed by a correction for the heterogeneity described by Δs within the propagation interval, which is done in the space domain. The wave field is transferred between the space and wavenumber domains using a fast Fourier transform. Since the propagator depends only on the local medium properties, access to the entire velocity structure of a model is not required to propagate through a portion of the model. This gives the method a computational advantage over some other wave equation-based methods. The method is valid for extrapolating the wave field so long as the primary direction of propagation is nearly parallel to the positive z direction and the variation in velocity is small in the direction perpendicular to z . Later extensions mentioned above have systematically improved the accuracy for large-angle waves in strongly varying media.

The SSF method has been used by Hoshiya (1999) in an investigation of the influences of random structure on amplitudes of seismic waves. Wu *et al.* (2000) developed a method similar to the SSF method for modeling Lg propagation in heterogeneous media. Spivack and Uscinski (1989) present an analytic and numerical investigation of the accuracy of the SSF method and conclude that it is reliable for calculating wave fields in random media but that it is even more reliable when computing transverse correlations of the wave field. There is a stochastic treatment of the phase screen method, which is called the Markov approximation (Lee and Jokipii, 1975a,b; Sreenivasiah *et al.*, 1976). This method directly gives the wave envelope in random media, and is applied to the study of seismogram envelope characteristics (Sato, 1989; Scherbaum and Sato, 1991; Obara and Sato, 1995). Fehler *et al.* (2000) have compared waveforms calculated for random media using finite difference, an extension of the SSF method, and the Markov approximation.

5. Summary and Discussion

Beginning from visual observations of the character of recorded seismograms that led to new ways of thinking about seismic wave propagation, the study of seismic wave scattering and attenuation has led to new and improved observational tools for characterizing the Earth. One reason that the coda normalization method has been so useful is because station calibration and/or site amplification could be eliminated so that other medium parameters could be measured. Recent theories about seismic wave propagation in heterogeneous media can also be applied to investigate envelope shape and additional information about lithospheric structure can be obtained from broadband calibrated data.

TABLE 1 Fundamental observations that have led to advances in using stochastic seismology to model scattered waves, theory and methods used to explain the observations, and the parameters that may be inferred from the methods

Observation	Theory and Interpretation Method	Parameters Estimated
Existence of coda	• Phenomenological • Coda normalization method • Single scattering approximation • Energy-flux model	• Coda attenuation • Scattering coefficient • Relative site amplification • Relative source factors
Envelope shape of local earthquakes	• Radiative transfer theory • Multiple lapse time window analysis	• Scattering coefficient • Seismic albedo (scattering loss, intrinsic absorption) • High-frequency radiation from fault
Attenuation	• Spectral decay with distance • Coda normalization method • Born approximation	• Fractional velocity fluctuation • Scale length (correlation length) of heterogeneity • Spectra of heterogeneity • Spatial variation of stochastic characterization of medium
Array phase/amplitude characteristics	• Diffraction/forward scattering • Parabolic wave equation and Rytov approximation • Theory of coherence analysis	
Envelope broadening of regional seismograms	• Diffraction/forward scattering • Parabolic wave equation • Markov approximation	

Table 1 summarizes fundamental observations that have led to advances in our understanding of stochastic wave phenomena in the Earth's lithosphere. The model or interpretation method used to understand each fundamental observation is listed along with the parameters that can be estimated by application of the models to real data. Many of the parameters can be estimated using deterministic models. In most cases, observations made using deterministic and random-wave approaches are complementary. In many cases, the stochastic approach provides parameters characterizing the Earth's lithosphere that cannot be obtained from deterministic measurements.

Our understanding of the structure of heterogeneity of the Earth's lithosphere as a function of scale is limited. While some data can be explained using well-defined correlation functions that have a narrow band of heterogeneity, this does not mean that heterogeneity is limited to a narrow band. One

fundamental issue facing those who investigate scattered waves is to find a unifying theory for a broad spectrum of seismic data that allows us to estimate the scale of heterogeneity over a broad range of scales.

Use of stochastic seismology has led to significant advances in our understanding of the character of seismic waveforms and enabled us to model portions of the waveforms that cannot be explained deterministically. The success of the models has improved our understanding of wave propagation in the Earth and led to the prediction of parameters that improve our understanding the structure and composition of the Earth's lithosphere.

Earthquakes as a Complex System

Donald L. Turcotte

Cornell University, Ithaca, New York, USA

Bruce D. Malamud

King's College London, UK

1. Introduction

Earthquakes are a direct consequence of the deformation of the Earth's crust. Parts of the crust are brittle, and significant deformation requires fractures to develop. Deformation across these fractures generates faults. Earthquakes are primarily associated with stick-slip behavior on these preexisting faults. Clearly these deformation processes are complex and occur on a wide range of scales. One approach to earthquake mechanics is to assume that displacements on a single (master) fault in a region are dominant and to neglect all other faults. Under this assumption, great earthquakes on the master fault occur on a near-periodic basis. This approach leads to the concept of seismic gaps—that regions where earthquakes have not occurred are regions where the next earthquake is expected (as was the case, for example, for the 1999 Izmit, Turkey earthquake).

An alternative approach to earthquake mechanics is to assume that the crust is a complex self-organizing system that can be treated by techniques developed in statistical physics; this is the main focus of this chapter. The basic hypothesis is that deformation processes interact on a range of scales from thousands of kilometers to millimeters or less. Evidence in support of this hypothesis comes from the universal validity of scaling relations. The most famous of these is the Gutenberg–Richter frequency–magnitude relation

$$\log \dot{N}_{CE} = -bm + \log \dot{a} \quad (1)$$

where $\dot{N}_{CE}$ is the cumulative number of earthquakes with a magnitude greater than m occurring in a specified area and time, and b and $\dot{a}$ are constants. In Section 2.1 we explore the validity of Eq. (1) for both regional and global earthquakes. The constant b , or “ b -value,” varies from region to region, but is generally in the range $0.8 < b < 1.2$ (Frohlich and Davis, 1993). The constant a is a measure of the regional

level of seismicity. There are a variety of measures for the magnitude, m , including local, body-wave, surface-wave, and moment magnitude (Lay and Wallace, 1995). In general, for small-intensity earthquakes ($m < 5.5$), the different magnitude measures give approximately equivalent results.

Sections 2.1–2.4 explore the idea that complex phenomena often exhibit fractal (power-law) scaling (Mandelbrot, 1982; Turcotte, 1997) in magnitude, space, and time. For earthquakes, fractal scaling of their magnitudes implies the validity of the relation

$$\dot{N}_{CE} = CA_E^{-D/2} \quad (2)$$

where $\dot{N}_{CE}$ is the cumulative number of earthquakes with rupture area greater than A_E occurring in a specified area and time; C and D are constants, with D the fractal dimension. Aki (1981) showed that Eqs. (1) and (2) are equivalent with

$$D = 2b \quad (3)$$

The universal applicability of the Gutenberg–Richter relation implies that the number of earthquakes scale with their rupture area according to power-law (fractal) scaling.

Complex phenomena often also exhibit chaotic behavior (Section 3.1). Lorenz (1963) considered a set of nonlinear differential equations that approximate thermal convection in a fluid. He showed that the deterministic solutions to these equations exhibit an exponentially diverging sensitivity to initial conditions. This is the definition of deterministic chaos. Based on this work, it is now generally accepted that the behavior of the oceans and atmosphere is chaotic.

Burridge and Knopoff (1967) introduced the slider-block model as an analogue for the stick-slip behavior of faults. Slider-block models will be discussed in detail in Sections 3.1 and 3.2. Huang and Turcotte (1990a) showed that slider-block models also exhibit deterministic chaos. This is taken as evidence that the behavior of the Earth's crust is also chaotic. Carlson and Langer (1989) considered long linear arrays of

slider blocks and concluded that they exhibit self-organized criticality.

The concept of self-organized criticality (Section 3.2) was introduced by Bak *et al.* (1988) as an explanation for the behavior of the cellular-automata “sandpile” model. Other models exhibiting self-organized critical behavior have been studied (Turcotte, 1999a). These models are characterized by a steady-state input and an output of “avalanches” that follow power-law (fractal) frequency–area distributions. Slider-block models clearly illustrate the transition from chaotic behavior (two slider blocks) to self-organized critical behavior (many slider blocks). The association of slider-block models with earthquakes provides strong evidence that earthquakes are an example of self-organized critical behavior in nature. One way to understand self-organized critical behavior is in terms of an inverse cascade of metastable clusters (Section 3.3), which grow and coalesce as strain occurs, giving a fractal frequency–area distribution.

Concepts of complexity have had direct applicability to probabilistic earthquake hazard studies (Section 4) and possibly to intermediate-term earthquake prediction (Section 5). The universal applicability of the Gutenberg–Richter relation, Eq. (1), provides one of the principal means of estimating the earthquake hazard. The rate of occurrence of small earthquakes provides a quantitative measure of the rate of occurrence of larger earthquakes. The concepts of complexity discussed in this chapter provide a rational basis for this extrapolation and possibly for intermediate-range earthquake prediction.

2. Fractal Distributions in Magnitude, Space, and Time

2.1 Gutenberg–Richter Relation

The best-known fractal (power-law) distribution in seismology is the Gutenberg–Richter frequency–magnitude relation, Eq. (1). This relation has been found to be valid both regionally and globally. As shown in Eq. (2), the b -value is equivalent to a fractal dimension D . The near universality of the b -value taking on values near unity is equivalent to a near-constant fractal dimension with $D \approx 2$. The fact that fractal dimensions are universal and not diagnostic is commonly found in applications (Turcotte, 1997). However, the constant a is a direct measure of the level of seismic activity in a region. This is one basis for estimating the seismic hazard, as will be shown in Section 4.

We first consider the worldwide number of earthquakes per year from the Harvard Centroid–Moment Tensor Database (1997) for the period 1977–1994. The seismic moments have been used to calculate moment magnitudes m and rupture areas A_E . In Figure 1, the cumulative number of earthquakes per year, $\dot{N}_{CE}$, with rupture area greater than A_E is given as

FIGURE 1 Worldwide cumulative, $\dot{N}_{CE}$, and noncumulative, $-d\dot{N}_{CE}/dA_E$, number of earthquakes per year with rupture area greater than A_E as a function of A_E . The data are from the Harvard Centroid–Moment Tensor Database (1997) for the years 1977–1994 with earthquake seismic moments converted to rupture areas A_E . The equivalent moment magnitudes m are also given.

a function of A_E , along with the equivalent moment magnitudes, m . The cumulative worldwide data per year correlate with Eq. (1) taking $b = 1.0$ ($D = 2.0$) and $\dot{a} = 10^8 \text{ y}^{-1}$.

The data in Figure 1 begin to deviate from the Gutenberg–Richter law, Eq. (1), for $m < 5.2$. This can be attributed to the resolution limits of the global seismic network. Regional studies indicate that good power-law correlations are obtained down to at least $m = 1$ (Aki, 1987). The deviation of data in Figure 1 from the Gutenberg–Richter relation for $m \geq 7.5$ is more controversial (Scholz, 1997). Clearly, there must be an upper limit to the size of an earthquake, but the deviations in Figure 1 can be attributed either to a real deviation from the correlation line or to the small number of very large earthquakes in the relatively short time span considered. There is a physical basis for a change in scaling for large earthquakes (Pacheco *et al.*, 1992). The rupture zone of smaller earthquakes is confined by the thickness of the seismogenic zone, say 20 km, whereas the length of the zone, l , can increase virtually without limit. Thus, for large earthquakes, $l \sim A_E$. The transition would be expected to occur for $A_E^{1/2} \approx 25 \text{ km}$ or $m \approx 7.0$.

Standard practice is to use cumulative distributions for earthquakes. However, this presents problems when making comparisons with models. Therefore, we wish to obtain a noncumulative distribution for global seismicity. Noncumulative distributions can be obtained by “binning” actual frequency–magnitude data and creating a histogram; however, care must be taken in how binning is carried out. If bins are linear, i.e., $r = 1-2, 2-3, 3-4, \dots$, and data have a power-law dependence of number of data in each bin on data size, $N_b \sim r^{-\alpha}$, then the

resulting cumulative distribution will be $N_{Cb} \sim r^{-a+1}$; the exponents differ by 1.0. However, if bins are logarithmic, i.e., $r = 1-2, 2-4, 4-8, \dots$, and data have a power-law dependence, $N_b \sim r^{-\beta}$, then the resulting cumulative distribution will be $N_{Cb} \sim r^{-\beta}$; the exponents are the same.

To avoid the difficulties of binning data, we use an alternative but equivalent approach to obtain a noncumulative distribution. We start with cumulative data, where N_{CE} is the number of earthquakes with area greater than A_E . The noncumulative distribution is the negative of the derivative of the cumulative distribution with respect to the area, $-dN_{CE}/dA_E$. The negative is because the cumulative distribution is summed from largest to smallest values. The derivative, $-dN_{CE}/dA_E$, is the slope from a specified number of adjacent cumulative data points. The noncumulative distribution given in Figure 1 uses five adjacent points to calculate the slopes of the cumulative distribution and a least-squares fit in log-log space. The noncumulative results given in Figure 1 correlate well with slope $b + 1 = 2$, as expected. We will return to noncumulative distributions when we consider models that exhibit self-organized critical behavior.

The remainder of our discussion will be restricted to cumulative distributions, as this is the standard practice in seismology when considering actual earthquakes. In our first example, we consider regional seismicity in Southern California. The cumulative frequency-magnitude distribution of seismicity in Southern California (SCSN Catalog, 1995) is given in Figure 2 for the period 1932–1994. Over the entire

FIGURE 2 Number of earthquakes per year, $\dot{N}_{CE}$, occurring in Southern California with body-wave magnitudes greater than m as a function of m . Also given is the square root of the equivalent rupture area. The solid line is data for the period 1932–1994 (SCSN Catalog, 1995). The straight dashed line is the correlation with Eq. (1) taking $b = 0.92$ ($D = 1.84$) and $\dot{a} = 1.40 \times 10^5 \text{ y}^{-1}$. The solid circle is the observed rate of occurrence of great earthquakes in Southern California (Sieh *et al.*, 1989).

range $4 < m < 7.5$ the data are in excellent agreement with Eq. (1) taking $b = 0.92$ and $\dot{a} = 1.4 \times 10^5 \text{ y}^{-1}$.

Dates for ten large earthquakes on the southern section of the San Andreas Fault have been obtained from radiocarbon dating of faults, folds, and liquefaction features (Sieh *et al.*, 1989). In addition to historical great earthquakes in 1857 and 1812, additional great earthquakes were estimated to have occurred in 1480, 1346, 1100, 1048, 997, 797, 734, and 671. The mean repeat time is 132 y ($\dot{N}_{CE} = 0.0076 \text{ y}^{-1}$). Sieh (1978) estimates $m = 8.25$ for the 1857 earthquake. Taking these values for $\dot{N}_{CE}$ and m , we obtain the solid circle in Figure 2. An extrapolation of the Gutenberg–Richter statistics (the dashed line in Figure 2) appears to make a reasonable prediction of great earthquakes on this section of the San Andreas Fault. Acceptance of this hypothesis allows the regional background seismicity to be used in assessing seismic hazards (Turcotte, 1989). The regional frequency-magnitude statistics can be extrapolated to estimate recurrence times for larger-magnitude earthquakes. Unfortunately, no information is provided on the largest earthquake to be expected in a region.

An important question in seismology is whether the occurrence of large plate-boundary earthquakes, such as those at subduction zones, can be estimated by extrapolating the regional seismicity as was done above for Southern California. This is a subject of considerable controversy. Some authors argue that the large earthquakes occur more often than would be predicted by an extrapolation (Davison and Scholz, 1985; Pacheco *et al.*, 1992; Camelbeeck and Meghraoui, 1996; Scholz, 1997).

To further consider the time dependence of regional seismicity, i.e., the time dependence of $\dot{a}$ in Eq. (1), we consider yearly seismicity in Southern California. In Figure 3, the cumulative number of earthquakes $\dot{N}_{CE}$ in each year between 1980 and 1994 (SCSN Catalog, 1995) with magnitudes greater than m is given as a function of m . In general, there is good agreement with Eq. (1) taking $b = 1.05$ and $\dot{a} = 2.06 \times 10^5 \text{ y}^{-1}$. The exceptions can be attributed to the aftershock sequences of the 1987 Whittier, 1992 Landers, and 1994 Northridge earthquakes. The linear correlation line in Figure 2 has a slope (b -value) that is slightly greater than the linear correlation line in Figure 3. This is because the data in Figure 2 include aftershocks, resulting in a higher percentage of smaller-magnitude events. With aftershocks removed, there is near uniformity from year to year in the background seismicity in Southern California. This result strongly suggests a thermodynamic behavior for seismicity in a region. It also suggests that the Earth's crust is continuously on the brink of failure (Scholz, 1991).

Since the eastern United States is a plate interior, the concept of rigid plates would preclude seismicity in the region. However, plates act as stress guides and forces that drive plate tectonics are applied at plate boundaries. Because plates are

FIGURE 3 Cumulative number of earthquakes per year, $\dot{N}_{CE}$, occurring in Southern California with magnitudes greater than m as a function of m . Fifteen individual years are considered (SCSN Catalog, 1995): (a) 1980–1984; (b) 1985–1989; (c) 1990–1994. The larger numbers of earthquakes in 1987, 1992, and 1994 can be attributed to the aftershocks of the Whittier, Landers, and Northridge earthquakes, respectively. The solid straight line in (a) to (c) is the Gutenberg–Richter relation Eq. (1) with $b=1.05$ and $\dot{a}=2.06 \times 10^5 \text{ y}^{-1}$, the best fit to the data, excluding 1987, 1992, and 1994.

essentially rigid, these forces are transmitted through their interiors. The plate interiors have zones of weakness that will deform under these forces, resulting in earthquakes. Thus earthquakes occur within the interior of the tectonic plates, although the occurrence frequencies are much lower than at plate boundaries.

As an example of intraplate seismicity we consider three great earthquakes that occurred in the Memphis–St. Louis (New Madrid, Missouri) seismic zone during the winter of 1811–1812. Johnston and Schweig (1996) suggest that two of these earthquakes had moment magnitudes $m \approx 8$. Based on instrumental and historical records, Johnston and Nava (1985) have given the frequency–magnitude statistics for earthquakes in this area for the period 1816–1983 (Fig. 4). The data correlate well with Eq. (1) taking $b=0.90$ ($D=1.80$) and $\dot{a}=2.24 \times 10^3 \text{ y}^{-1}$. Comparing Figures 4 and 2, the probability of having a moderate-sized earthquake in the Memphis–St. Louis seismic zone is about 1/60 the probability of having a similar magnitude earthquake in Southern California. Assuming that it is valid to extrapolate the data in Figure 4 to larger earthquakes, a magnitude $m \approx 8$ would have a recurrence time of about 7000 y.

We have considered two seismic regions, Southern California and the Memphis–St. Louis seismic zone, to illustrate the regional validity of the Gutenberg–Richter relation. Many other regions could have been considered. The universal validity of this relation is remarkable and any comprehensive theory for seismicity should explain it. We will now explore other fractal (power-law) relations in seismicity.

FIGURE 4 The cumulative number of earthquakes per year, $\dot{N}_{CE}$, occurring in the New Madrid, Missouri seismic zone (1816–1983) with magnitudes greater than m as a function of m . The open circles represent instrumental data and the solid circles historical data (Johnston and Nava, 1985). The straight dashed line is the Gutenberg–Richter relation Eq. (1) with $b=0.90$ and $\dot{a}=2.24 \times 10^3 \text{ y}^{-1}$.

2.2 Omori's Law

Earthquakes are universally followed by a sequence of aftershocks. A power-law decay in the number of aftershocks, $R(t)$, as a function of time t after the main shock takes the form

$$R(t) \sim \frac{1}{(t_0 + t)^\rho} \quad (4)$$

with t_0 and ρ being fitting constants. This relation is also found to be universally valid, with the constant ρ taking on values near unity, and is known as Omori's law (Utsu, 1961; Utsu *et al.*, 1995). Again this power-law relation requires a universal explanation.

2.3 Spatial Distribution of Faults

There are two end-member models that give fractal spatial distributions of earthquakes. The first is that the spatial distribution of faults is fractal and each fault has earthquakes of a single size (rupture area equal to fault area). The second is that each fault has a spatial distribution of earthquakes on it that is fractal. A variety of observations favor the first hypothesis. For example, on the northern and southern locked sections of the San Andreas Fault, there is no evidence for a fractal distribution of earthquakes. Great earthquakes occurred on the northern and southern sections in 1906 and 1857, respectively. Great earthquakes and their associated aftershock sequences occur, but between these great earthquakes, seismicity is essentially confined to secondary faults. A similar statement can be made about the Parkfield section of the San Andreas Fault, where moderate-sized earthquakes occurred in 1881, 1901, 1924, 1934, and 1966. There is no evidence for a fractal spatial distribution of events on this section of the San Andreas Fault. We therefore conclude that a reasonable working hypothesis is that each fault has earthquakes of a single size and a fractal spatial distribution of earthquakes implies a fractal spatial distribution of faults.

Although we can conclude that the frequency–size distribution of faults is fractal, the fractal dimension is not necessarily the same as that for earthquakes. Equal fractal dimensions would imply that the interval of time between earthquakes is independent of scale. This need not be the case. It is generally difficult to quantify the frequency–size distribution of faults, as many faults are not recognized until earthquakes occur on them. Coal mining areas provide access to faults and fractures at depth. The cumulative distributions of the number of faults N_{CF} with lengths greater than r are given in Figure 5 for two coal mining areas (Villemin *et al.*, 1995). Correlations with the fractal scaling relation, Eq. (2), are given with $D = 1.6$. Other compilations of number–length statistics of faults, and comparisons with power-law correlations, have been given by Gudmundson (1987), Hirata (1989), and Main *et al.* (1990).

FIGURE 5 Cumulative number of faults, N_{CF} , with lengths greater than r as a function of r . The boxes are measurements in the Lorraine coal basin and the circles from the Vernejoul coal field (Villemin *et al.*, 1995). Correlations with the fractal scaling relation Eq. (2) are given with $D = 1.6$.

2.4 Spatial Distribution of Earthquakes

We next turn to the spatial distribution of earthquakes. A basic question is whether the spatial distribution is random (Poissonian) or fractal (scale-invariant). Studies of this problem require accurate locations of earthquakes with magnitudes above a specified minimum. Because of the deployment of high-density seismic arrays, the best spatial resolution data are for aftershock sequences. Robertson *et al.* (1995) have studied 3D (three-dimensional) spatial distributions of aftershocks using the box-counting method. These authors considered the aftershock sequences of the $m = 6.1$ Joshua Tree earthquake of 23 April 1992 (2600 events in a $20 \times 20 \times 19 \text{ km}^3$ volume in 160 days) and the $m = 6.2$ Big Bear earthquake of 28 June 1992 (818 events in a $20 \times 20 \times 17 \text{ km}^3$ volume in 375 days).

Figure 6 shows the number of cubes occupied by at least one earthquake as a function of cube linear dimension (0.5–20 km) for the two aftershock sequences. The data are in good agreement with Eq. (2) taking $D = 2.0$. A fractal dimension of 2 would be expected if the earthquakes lie on a plane; however, there is considerable 3D structure to the aftershock sequences. This led Robertson *et al.* (1995) to suggest that the earthquakes form the “backbone” of a percolation cluster, which we now discuss.

One of the standard models in statistical physics is the site-percolation model (Stauffer and Aharony, 1992). In the 2D (two-dimensional) version of this model a square array is made up of a matrix of boxes; each box may be either permeable or impermeable. The probability that a box is permeable is p_0 , $0 \leq p_0 \leq 1$; the probability it is impermeable is $(1 - p_0)$.

FIGURE 6 Three-dimensional spatial distributions of two aftershock sequences have been analyzed using the box-counting method (Robertson *et al.*, 1995). The aftershock sequence of the $m = 6.1$ Joshua Tree earthquake of 23 April 1992 (2600 events in a $20 \times 20 \times 19 \text{ km}^3$ volume in 160 days), and the aftershock sequence of the $m = 6.2$ Big Bear earthquake of 28 June 1992 (818 events in a $20 \times 20 \times 17 \text{ km}^3$ volume in 375 days) are considered. The number of cubes, N , occupied by one or more earthquakes is given as a function of the cube linear dimension, r , for the two aftershock sequences; cubes with $0.5 < r < 20 \text{ km}$ were used. The correlation with the fractal scaling relation Eq. (2) is given with $D = 2.0$.

The question is whether the square array is permeable or impermeable. The array is defined to be permeable if there is a continuous path of permeable boxes from the top to the bottom of the array. This is clearly a statistical question since the actual distribution of permeable and impermeable boxes is random. For a specified value of p_0 there is a probability P that the square array of boxes is permeable. The critical probability for the percolation threshold is given by p^* . For large arrays, it is found that P is very small ($P \ll 1$) if $0 \leq p_0 \leq p^*$ and that P is near unity ($P \approx 1$) if $p^* < p_0 \leq 1$ (Stinchcombe and Watson, 1976). The value of p_0 that corresponds to the onset of flow through the array is the critical value and denoted by p^* . If $p_0 < p^*$, a large square grid will almost certainly be impermeable to flow; if $p_0 \geq p^*$, it will be permeable. Using the Monte Carlo approach, a large number of random realizations can be carried out and the probability $P(p_0)$ that the array is impermeable can be determined. For a square array with large n , numerical simulations find that the critical probability for the onset of flow in the array is $p^* = 0.59275$ (Stauffer and Aharony, 1992). The cluster of sites belonging to this permeable path is known as the percolation backbone.

The site-percolation threshold is a critical point and a variety of critical-point scalings are found (Stauffer and Aharony, 1992). This simple model can also be discussed in terms of fractures. As the stress on a thin sheet is increased, random ruptures will appear. Eventually these ruptures will coalesce to

form a through-going rupture that crosses the sheet. The critical stress leading to the failure can be considered a critical point of the problem.

The site-percolation problem can also be considered in 3D where each box in a cubic array is assigned a probability of being permeable. The critical probability for the percolation backbone that crosses the cube is found to be $p^* = 0.3117$ (Stauffer and Aharony, 1992). This backbone has a fractal dimension close to 2. Sahimi *et al.* (1992, 1993) explained the fractal spatial distribution of aftershocks illustrated in Figure 6 as being the result of a 3D percolation backbone.

The box-counting technique has been applied to both the temporal and 2D spatial distributions of earthquakes in Japan by Bodri (1993). The temporal clustering of seismicity has been studied by Sadovsky *et al.* (1984) and by Smalley *et al.* (1987). The latter authors considered the temporal variations of seismicity in several regions in the New Hebrides island arc for the period 1978–1984. In each case, fractal temporal and spatial distributions were found.

3. Slider-Block Models: Chaos and Self-Organized Criticality

3.1 Deterministic Chaos

Lorenz (1963) discovered deterministic chaos. He derived three coupled total differential equations as an approximation for thermal convection in a fluid layer heated from below. He showed that solutions in a parameter range had an exponentially diverging sensitivity to initial conditions. This divergent behavior is the definition of chaotic behavior. The chaotic behavior of these equations has been taken as evidence that the atmosphere and oceans are chaotic.

Burridge and Knopoff (1967) introduced the slider-block model as a simple model for the behavior of a fault. One can show that a pair of connected slider blocks can exhibit deterministic chaos (Huang and Turcotte, 1990a; McCloskey and Bean, 1992). Consider the behavior of a pair of slider blocks as illustrated in Figure 7. A constant-velocity driver drags the blocks over the surface at a mean velocity, v . The two blocks are coupled to each other by a spring with spring constant k_c and to the driver plate by springs with spring constant k_p . Other model parameters are the block masses m and the frictional forces F_{s1} and F_{s2} . Solutions are governed by two parameters, the stiffness of the system k_c/k_p and the ratio of static to dynamic friction F_s/F_d . For some values of these parameters, deterministic chaos is found. Otsuka (1972) considered a 2D array of slider blocks and obtained a power-law frequency–area distribution for slip events.

A modification to the analysis of a pair of slider blocks is to allow only one slider block to slip at a time. When a slider block becomes unstable, it is allowed to complete its harmonic motion before the stability of the second slider block is

FIGURE 7 Behavior of a pair of slider blocks. A constant-velocity driver drags the blocks with mass m over the surface at a mean velocity v . The two blocks are coupled to each other by a spring with spring constant k_c and to the driver plate by springs with spring constant k_p . Frictional forces are F_{s1} and F_{s2} .

determined; if it is unstable, it is allowed to carry out its harmonic motion. The primary advantage of this modification is that slider-block displacements are given by analytical expressions and numerical solutions of differential equations are not required. Studies of this modified slider-block problem (Narkounskaia and Turcotte, 1992; Narkounskaia *et al.*, 1992) yield a variety of behaviors including periodic and chaotic solutions.

Huang and Turcotte (1990b) have applied the chaotic behavior of the asymmetric two-block system to two examples of interacting fault segments. In the first, the Philippine Sea plate descends beneath the Asian plate, resulting in the formation of the Nankai trough along the coast of southwestern Japan. The relative motion between the plates has resulted in a sequence of great earthquakes that have been documented through historical records, AD 684–1946. The sequence is marked by an irregular but somewhat repetitive pattern in which whole-section failures occur following several alternative failures of single segments. In the two-block model, the simultaneous slip of both blocks corresponds to an earthquake that ruptures the entire section, and single-block failures correspond to an earthquake on a single segment. Huang and Turcotte (1990b) found chaotic model behavior that strongly resembled the observed sequence of earthquakes in the Nankai trough.

The second example is the interaction between the Parkfield segment and the rest of the south-central locked segment of the San Andreas Fault in California. A sequence of $m \approx 6$ earthquakes occurred in 1857 and were also associated with a rupture on the Parkfield segment. Huang and Turcotte (1990b) found chaotic model behavior similar to that described above. A sequence of slip events on the weaker block often preceded the simultaneous slip of the weaker and stronger blocks. The model simulation suggested two alternative scenarios for a great Southern California earthquake

following a sequence of Parkfield earthquakes. In the first scenario, a Parkfield earthquake will transfer sufficient stress to trigger the great Southern California earthquake; the Parkfield earthquake is thus essentially a foreshock for the great earthquake. In the second scenario, a small additional strain after a Parkfield earthquake will trigger an earthquake on the southern section, resulting in additional displacement on the Parkfield section. The evolution of the system is chaotic; its evolution is not predictable except in a statistical sense.

Slider-block models are a simple analogy to the behavior of faults in the Earth's crust. However, the chaotic behavior of low-dimensional analog systems often indicates that natural systems will also behave chaotically. Thus, it is reasonable to conclude that the interactions between faults that lead to fractal (power-law) frequency–magnitude distributions are an example of deterministic chaos. The prediction of earthquakes is not possible in a deterministic sense. Only a probabilistic approach to the occurrence of earthquakes will be possible.

3.2 Self-Organized Criticality

One explanation for fractal statistics is scale invariance. The power-law distribution is the only statistical distribution that does not require a characteristic length scale. Thus, natural phenomena that do not inherently have a natural length scale would be expected to obey power-law (fractal) statistics. However, there may be a more fundamental basis for the applicability of fractal statistics. In the past ten years, a variety of numerical models have been found to exhibit a universal behavior that has been called self-organized criticality. In self-organized criticality the “input” to a complex system is slow and steady; whereas, the output is a series of events or “avalanches” that follow power-law frequency–size statistics. Regional seismicity is often taken as a naturally occurring example of self-organized criticality. The input is the motion of the tectonic plates and the output is the earthquakes.

The concept of self-organized criticality was introduced by Bak *et al.* (1988) as an explanation for the behavior of the “sandpile” model. In this model, a square array of boxes is considered and at each time step a particle is dropped into a randomly selected box. When a box accumulates four particles, they are redistributed to the four adjacent boxes, or in the case of edge boxes they are lost from the grid. Because the redistributions involve only nearest-neighbor boxes, it is known as a cellular-automata model. Redistributions of particles can lead to further instabilities with, at each step, the possibility of avalanches of particles being lost from the grid. Each of the multiple redistributions during a time step contribute to the size of the model “avalanche”.

This model was called a “sandpile” model because of the resemblance to an actual sandpile on a table. The randomly dropped particles in the model are analogous to the addition of particles to an actual sandpile. The model avalanches are analogous to sand avalanches down the sides of the sandpile.

In some cases the sand avalanches lead to the loss of particles off the table. Extensive numerical studies of the “sandpile” model were carried out by Kadanoff *et al.* (1989). They found the noncumulative frequency–area distribution of avalanches to have a power-law distribution with a slope near unity.

A second example of “self-organized criticality” is the behavior of large arrays of slider blocks. The two-block model was considered in the last section. The standard multiple slider-block model consists of a square array of slider blocks as illustrated in Figure 8. Each block with mass m is attached to the driver plate with a driver spring, spring constant k_p . Adjacent blocks are attached to each other with a connector spring, spring constant k_c . The constant-velocity driver plate is pulled forward with velocity v . A block remains stationary as long as the net force on the block is less than the static resisting force, F_s . Again, two parameters determine the behavior of the system, the ratio of static to dynamic friction, F_s/F_d , and the stiffness of the system, k_c/k_p .

Carlson and Langer (1989) considered long linear arrays of slider blocks with each block connected by springs to the two neighboring blocks and to a constant-velocity driver. They used a velocity weakening friction law and considered up to 400 blocks. Slip events involving large numbers of blocks were observed, the motions of all blocks involved in a slip event were coupled, and the applicable equations of motion had to be solved simultaneously. Although the system was completely deterministic, the behavior was apparently chaotic. Frequency–area statistics were obtained for slip events. The events fell into two groups: Smaller events obeyed a power-law (fractal) relationship with a slope near unity, but there were

an anomalously large number of large events that included all the slider blocks. The observed behavior was characteristic of self-organized criticality. The motion of the driver plate is the steady input. The slip events are the “avalanches” with a power-law (fractal) frequency–size distribution.

Nakanishi (1990, 1991) studied multiple slider-block models using the cellular-automata approach. A linear array of slider blocks was considered but only one block was allowed to move in a slip event. The slip of one block could lead to the instability of either or both of the adjacent blocks, which would then be allowed to slip in a subsequent step or steps, until all blocks were again stable. Brown *et al.* (1991) proposed a modification of this model involving a 2D array of blocks. The use of cellular automata greatly reduces the complexity of the calculations and the results using the two approaches are generally very similar. A wide variety of slider-block models have been proposed and studied; these have been reviewed by Carlson *et al.* (1994) and Turcotte (1999a).

Huang *et al.* (1992) carried out a large number of simulations on a square array of blocks using stick-slip friction and the cellular-automata approach. Their noncumulative frequency–area statistics for model slip events are given in Figure 9. The number of slip events per time step N_e/N_T with area A_e is given as a function of A_e . The simulation results are well fit by the power-law scaling relation Eq. (2) with $D=2.72$. For stiff systems (k_c/k_p large), the entire grid of slider blocks is strongly correlated and large slip events including all the blocks occur regularly. These are the peaks for $A_e=400$, 900, and 1600 blocks, illustrated in Figure 9. For soft systems (k_c/k_p relatively small), no large events occur.

FIGURE 8 Illustration of the 2D slider-block model with multiple blocks. An array of blocks, each with mass m , is pulled across a surface by a driver plate at a constant velocity, v . Each block is coupled to adjacent blocks with either leaf or coil springs (spring constant k_c), and to the driver plate with leaf springs (spring constant k_p).

FIGURE 9 Results for a 2D slider-block model with multiple blocks (Huang *et al.*, 1992). The ratio of the number of slip events N_e with area A_e to the total number of time steps N_T is plotted against A_e , the number of blocks involved in an event. Results are for systems with stiffness $k_c/k_p = 30$, friction $F_s/F_d = 1.5$, and grid sizes 20×20 , 30×30 , 40×40 , and 50×50 blocks. The peaks at $A_e = 400, 900$, and 1600 blocks correspond to catastrophic events involving the entire system.

3.3 Cascade Model

A simple inverse-cascade model can explain the self-organized critical behavior of slider-block arrays (Turcotte *et al.*, 1999; Turcotte, 1999b). A metastable cluster is the region over which a slip event propagates once it has been initiated. At any one time, there can be many metastable clusters on the grid. From Figure 9 the number of slip events N_e of size A_e can be related to the number of slip events that involve a single block N_{e0} by

$$N_e = \frac{N_{e0}}{A_e^{1.36}} \quad (5)$$

where A_e , the area, is the number of slider blocks participating in the slip event.

We assume that the probability that a slip event is triggered in a metastable cluster is proportional to the area of the cluster itself. Thus the number N_m of metastable clusters with area A_e on the grid at any one time is related to the number N_e of slip events over time with the same area A_e by

$$N_e \sim N_m A_e \quad (6)$$

It is also appropriate to assume that the number of metastable clusters satisfies the relation

$$N_m = \frac{N_{m0}}{A_e^\gamma} \quad (7)$$

where γ is a constant and N_{m0} is the number of metastable clusters with only one slider block. In order for Eqs. (5) and (7)

to satisfy Eq. (6), the constant $\gamma = 2.36$. The cumulative number N_{Cm} of metastable clusters larger than A_e is given approximately by

$$N_{Cm} = N_{m0} \int_{A_e}^{\infty} \frac{dA}{A^{2.36}} = \frac{N_{m0}}{1.36 A_e^{1.36}} \quad (8)$$

and is inversely proportional to area to the 1.36 power.

The inverse-cascade model assumes that metastable clusters grow by combining. The process is referred to as an inverse cascade because it proceeds from the smallest to the largest scales. In the model it is assumed that the metastable clusters contain $A_n = 2^n$ blocks with $n = 0, 1, 2, 3, \dots, N$ (i.e., $A_n = 1, 2, 4, 8, \dots, 2^N$ blocks). This is equivalent to logarithmic binning. The number of clusters with A_n particles is denoted by N_n with $n = 0, 1, 2, 3, \dots, N$. Differential equations are written for the set of N_n and take the form

$$\frac{dN_0}{dt} = C_0 - C_{0,1}N_0^2 - D_0N_0 \quad (9)$$

$$\frac{dN_n}{dt} = \frac{1}{2}C_{n-1,n}N_{n-1}^2 - C_{n,n+1}N_n^2 - D_nN_n \quad (10)$$

The constant C_0 is the rate at which single blocks become metastable due to the driver plate motion. The net force on the block is greater than the dynamic friction. The transition probability $C_{0,1}$ is the rate at which single metastable blocks become pairs of metastable blocks at level $n = 1$. The constant D_0 is the rate at which clusters of one block are lost due to slip events. In the cascade model, it is assumed that metastable clusters of size 2^n are obtained by the merging of two clusters of size 2^{n-1} . The metastable clusters grow in size due to the motion of the driver plate. The rate at which metastable clusters of size 2^{n-1} merge to give metastable clusters of size 2^n is $\frac{1}{2}(C_{n-1,n}N_{n-1}^2)$. This is equivalent to a collision probability for metastable clusters; since each metastable cluster can merge with the N_{n-1} other metastable clusters, the probability is proportional to N_{n-1}^2 . Similarly, metastable clusters of size 2^n are lost as they merge to form metastable clusters of size 2^{n+1} ; the rate at which this occurs is $C_{n,n+1}N_n^2$. Metastable clusters of size 2^n are also lost in slip events at a rate D_nN_n ; the loss rate is proportional to the number of metastable clusters of that size.

The cascade model is a renormalization group approximation in the sense that metastable clusters are binned into sizes 2^n . It is also necessary to specify how the transition probabilities $C_{n,n+1}$ and loss rate D_n depend on the metastable cluster area 2^n . For the transition probabilities we assume a power-law dependence on cluster area, but do not specify the exponent:

$$C_{n,n+1} = \frac{(2^n)^\epsilon C_0}{N_R^2} \quad (11)$$

where ε and N_R are constants. We assume the loss rates are proportional to metastable cluster areas, so that

$$D_n = 2^n \beta \frac{C_0}{N_R} \quad (12)$$

where β is a constant.

We can absorb the constant C_0 into the definition of time with no loss of generality by introducing

$$\tau = C_0 t \quad (13)$$

Substitution of Eqs. (11) to (13) into (9) and (10) gives

$$\frac{dN_0}{d\tau} = 1 - \left(\frac{N_0}{N_R}\right)^2 - \beta \left(\frac{N_0}{N_R}\right) \quad (14)$$

$$\frac{dN_n}{d\tau} = \frac{1}{2} (2^{n-1})^\varepsilon \left(\frac{N_{n-1}}{N_R}\right)^2 - (2^n)^\varepsilon \left(\frac{N_n}{N_R}\right)^2 - 2^n \beta \left(\frac{N_n}{N_R}\right) \quad (15)$$

The behavior of this inverse-cascade model is illustrated in Figure 10. The steady-state solution to this set of equations is obtained by setting $dN_n/d\tau = 0$, with the result

FIGURE 10 Schematic flow diagram for the inverse-cascade model. Clusters of size 2^0 combine to form clusters of size 2^1 with probability $\alpha A_0 N_0^2$ (where $A_0 = 2^0$) and clusters of size 2^0 are lost in slip events with a probability $\beta A_0 N_0$. Similarly, clusters of size 2^1 combine to form clusters of size 2^2 with probability $\alpha A_1 N_1^2$ (where $A_1 = 2^1$) and clusters of size 2^1 are lost in slip events with a probability $\beta A_1 N_1$.

$$\frac{N_0}{N_R} = \frac{1}{2} \left[-\beta + (\beta^2 + 4)^{1/2} \right] \quad (16)$$

$$\frac{N_n}{N_R} = \frac{1}{2^{n\varepsilon+2}} \left\{ -2^{n+1}\beta + \left[2^{2n+2}\beta^2 + 2^{(2n-1)\varepsilon+3} \left(\frac{N_{n-1}}{N_R} \right)^2 \right]^{1/2} \right\} \quad (17)$$

This system generates an inverse cascade if $\beta \ll 1$, and Eqs. (16) and (17) become

$$\frac{N_0}{N_R} = 1 \quad (18)$$

$$\frac{N_n}{N_R} = \frac{1}{2^{(\varepsilon+1)/2}} \left(\frac{N_{n-1}}{N_R} \right) \quad (19)$$

Using Eqs. (18) and (19) we can write

$$\begin{aligned} \frac{N_n}{N_R} &= \frac{N_n}{N_0} = \left(\frac{N_1}{N_0} \right) \left(\frac{N_2}{N_1} \right) \left(\frac{N_3}{N_2} \right) \cdots \left(\frac{N_n}{N_{n-1}} \right) = \left(\frac{N_n}{N_{n-1}} \right)^n \\ &= \left(\frac{1}{2^{(\varepsilon+1)/2}} \right)^n = \left(\frac{1}{2^n} \right)^{(\varepsilon+1)/2} \end{aligned} \quad (20)$$

and with $A_n = 2^n$ this result gives

$$\frac{N_n}{N_R} = \frac{1}{A_n^{(\varepsilon+1)/2}} \quad (21)$$

The logarithmic binning used in this model is equivalent to a cumulative distribution. Taking $\varepsilon = 1.72$, Eq. (21) is identical

FIGURE 11 Frequency-area distribution for clusters obtained from the inverse-cascade model Eq. (17). The number of clusters N_n of size $A_n = 2^n$, divided by the reference number N_R , is given as a function of A_n for $\beta = 10^{-2}$ and 10^{-3} .

to those results obtained from the slider-block model, Eq. (8). Our simple inverse-cascade model reproduces the frequency–size distribution that is a characteristic of self-organized critical behavior.

As a specific example of the inverse-cascade model we take $\varepsilon = 1.72$ and in Figure 11 give the distribution of cluster sizes from Eq. (17) with $A_n = 1.72$ substituted. Distributions are given for $\beta = 10^{-2}$ and 10^{-3} . The parameter β plays the same role as the stiffness α in the results for the slider-block model given in Figure 9.

4. Earthquake Hazard Assessment

Presently, we cannot predict earthquakes in the way we predict volcanic eruptions. Seismic activation, surface uplift, and chemical emissions systematically precede major volcanic eruptions. No precursory phenomena have been recognized to occur systematically prior to earthquakes (Turcotte, 1991). However, we can provide rational assessments of the seismic hazard. To a first approximation, major earthquakes are restricted to the plate boundaries of plate tectonics. However, some of these boundaries are quite diffuse in continental areas (e.g., the western United States and much of China). Major earthquakes also occur within plate interiors (e.g., New Madrid, Missouri).

Seismic hazard maps have been prepared for many parts of the world. For the United States, the US Geological Survey's June 1996 maps (Frankel *et al.*, 1996) are available on the Internet. Seismic hazard maps generally give the probability of exceeding a specified peak ground acceleration during a specified time interval. The data used to formulate the maps include the historic seismicity discussed in this paper, maps of active faults, and levels of seismic attenuation. Techniques for seismic hazard assessment can be deterministic and probabilistic. Deterministic assessments are based on the previous occurrence of earthquakes of the magnitude to be considered. This occurrence can be based on recent instrumental records, older historic records, studies of the paleoseismic record using techniques such as trenching, and the presence of recently active "capable" faults. This approach follows from classical mechanics models for seismicity that leads to assumptions of quasi periodicity in earthquake occurrence.

Probabilistic hazard assessments are based on extrapolations of available data. The validity of the Gutenberg–Richter frequency–magnitude relation, Eq. (1), for regional seismicity has been recognized for some fifty years. The use of this relation to extrapolate the rate of occurrence of small earthquakes to larger earthquakes (Cornell, 1968) has been routinely incorporated into many regional seismic hazard assessments in a number of developed countries. Frankel (1995) proposed a systematic extrapolation technique for the Eastern United States. First, the region was divided into

$11 \times 11 \text{ km}^2$ cells. Then, the number of earthquakes N_i in each cell i , with magnitudes greater than a given m was determined. The grid of N_i values was spatially smoothed using a Gaussian function with a correlation distance c . A map of smoothed 10^4 values was prepared (Frankel, 1995, figure 4) taking $m = 3$ (1924–1991) and $c = 50 \text{ km}$. The optimal c -value of about 50 km was found through trial and error.

Turcotte (1999b) and Kossobokov *et al.* (2000) have proposed a similar technique for assessing the seismic hazard globally. Their extrapolation utilized the epicenters of earthquakes with magnitudes $m \geq 4$, where the data were obtained from the NEIC Global Hypocenter Database (GHDB, 1989) for the period 1964–1995. A magnitude 5 cut-off was also considered. The advantage of a magnitude 5 cut-off is that the database is globally complete for earthquakes $m \geq 5$ during this period (Engdahl *et al.*, 1998). The advantage of the magnitude 4 cut-off is that there are many more earthquakes on which to base statistics. Since the primary goal was to provide the best seismic hazard assessment in populous regions, and since these regions generally have seismic networks that provide a complete catalog for $m \geq 4$ during this period, this value was chosen for the cut-off.

The surface of the Earth was divided into $1^\circ \times 1^\circ$ regions and the number of earthquakes per year with magnitudes $m \geq 4$ in each region was determined. Each $1^\circ \times 1^\circ$ region varied in area with respect to changing latitude and they were therefore scaled by using the cosine of the latitude as a normalizing factor. The seismic intensity factor, I_4 , is defined to be the (normalized) number of magnitude $m \geq 4$ earthquakes that have occurred in a given $1^\circ \times 1^\circ$ region per year. The minimum value of the seismic intensity factor considered is $I_4 = 1/32 \text{ y}^{-1}$, one magnitude $m \geq 4$ earthquake in the 32-year period considered. The maximum value of the seismic intensity factor is about $I_4 = 40 \text{ y}^{-1}$ (40 magnitude $m \geq 4$ earthquakes per year).

A global map of the seismic intensity factor is given in Color plate 5(a). The boundaries of plate tectonics are clearly defined. Seismicity is particularly intense in subduction zones (i.e., the ring of fire around the Pacific) as expected. A broadband of seismicity extends from southern Europe to southeast Asia; this is associated with the continent–continent collision zone between the Eurasian plate and the African, Arabian, and Indian plates.

In Figure 12, we give two regional maps of the seismic intensity factor, I_4 . For the United States (Fig. 12a) the intense seismicity along the Pacific–North American plate boundary, including the San Andreas Fault, is clearly illustrated. The distributed seismicity associated with the intraplate deformation in the western United States (the Basin and Range province) is also shown. The most intense seismicity in the eastern United States is the Memphis–St. Louis seismic zone (36° N , 90° W). For Europe (Fig. 12b), the Aegean region has particularly intense seismicity, but high levels of seismicity extend throughout the Mediterranean area.

FIGURE 12 Regional maps of the seismic intensity factor, I_4 , the average annual number of earthquakes per year during 1964–1995 with magnitudes $m \geq 4$ in each normalized $1^\circ \times 1^\circ$ cell (Kossobokov *et al.*, 2000) for (a) United States and (b) Europe. Data from the NEIC Global Hypocenter Database (GHDB, 1989).

The basis for using the seismic intensity factor I_4 is illustrated in Figure 13. For five values of I_4 , the cumulative number of earthquakes per year, $\dot{N}_{CE}$, in a $1^\circ \times 1^\circ$ area, with magnitudes $m \geq 4$ are plotted as a function of m . The different lines are derived using the Gutenberg–Richter relation Eq. (1) with $b=0.9$, and calculating $\dot{a}$ from $\log \dot{a} = 3.6 + \log I_4$. Given a region with $I_4 = 1 \text{ y}^{-1}$, an earthquake with $m \geq 6$ has a return period of 63 y ($\dot{N}_{CE} = 0.016$) and one with $m \geq 8$ has a return period of 4000 y ($\dot{N}_{CE} = 0.00025$).

It can be argued that the use of earthquakes with $m \geq 4$ for such a short period (37 y) would not represent the

long-term seismic hazard. To address this concern, we have used the NEIC Global Hypocenter Database (GHDB, 1989) to determine the largest earthquake occurring in each $1^\circ \times 1^\circ$ area for the period 1900–1997. These data are given in Color plate 5(b). Comparing parts (a) and (b) in Color plate 5, it is seen that there is a strong correlation between the value of the earthquake intensity factor, I_4 , and the largest earthquake to have occurred in each $1^\circ \times 1^\circ$ area.

The primary advantage of this approach is that it is totally based on a generally accepted data set. There are no ambiguities with regard to the technique. This is not the case for

FIGURE 13 Similarity basis for extending the seismic intensity factor I_4 to higher earthquake magnitudes. For $I_4 = 0.01, 0.1, 1, 10$, and 100 y^{-1} , the cumulative number of earthquakes per year in a $1^\circ \times 1^\circ$ area, $\dot{N}_{CE}$, with magnitudes greater than m are plotted as a function of m . Each line is derived by using the Gutenberg–Richter relation, Eq. (1), with $b = 0.9$, and calculating the constant $\dot{a}$ from $\log \dot{a} = 3.6 + \log I_4$.

other approaches to assessing the seismic hazard, which combine geophysical and geological observations in arbitrary ways. Different studies give different weights to historical and paleoseismic data, and to the presence of “active” faults. Considering the many uncertainties regarding fault depth, seismic attenuation, available database, and the occurrence of an earthquake on a particular fault, this approach, which is based on the universal applicability of Gutenberg–Richter scaling, provides a reasonable basis for assessing the seismic hazard.

5. Intermediate-Term Earthquake Prediction

5.1 Pattern Recognition

Based on pattern recognition algorithms, a number of intermediate-range earthquake prediction algorithms were developed at the International Institute of Earthquake Prediction Theory and Mathematical Geophysics in Moscow (Keilis-Borok, 1990; Keilis-Borok and Kossobokov, 1990; Keilis-Borok and Rotwain, 1990; Kossobokov *et al.*, 1997). The pattern recognition includes quiescence (Schreider, 1990), increases in the clustering of events, and changes in aftershock statistics (Molchan *et al.*, 1990). The first algorithm, *M8*, was developed to make intermediate predictions of the largest earthquakes ($m > 8$). This method utilizes overlapping circles of seismicity with diameters of 384, 560, 854, and 1333 km for

earthquakes, with magnitudes 6.5, 7.0, 7.5, and 8.0, respectively. Within each circle four quantities are determined. The first three are measures of intermediate levels of seismicity and the fourth is a measure of aftershock activity.

The first quantity that must be specified is the lower magnitude cut-off $m_{\min}$ for earthquakes to be considered in the circle. Two magnitude cut-offs are considered for each circular region. The long-term number of earthquakes per year N in the circle with magnitudes greater than $m_{\min}$ is determined; $m_{\min 10}$ corresponds to $N = 10$ and $m_{\min 20}$ corresponds to $N = 20$. The first quantity $N_1(t)$ is the number of earthquakes per year with magnitudes greater than $m_{\min 20}$. The second quantity is the 5-year trend in activity $L_1 = dN_1/dt$ and $L_2 = dN_2/dt$ for running 5-year windows. Clearly $N(t)$ and $L(t)$ are strongly correlated. The third quantity, $Z_1(t)$ or $Z_2(t)$, is the ratio of the average linear dimension of rupture to average separation between earthquakes for a year in a circle. The final measure is the number of aftershocks in a specified magnitude range and time window following a main shock. This quantity $B(t)$ is a measure of aftershock activation.

Since N , L , and Z are determined for both $N = 10$ and 20 y^{-1} , there are seven time-series to be considered. An earthquake alarm or time of increased probability (TIP) is issued if six of the seven quantities, including B , exceed their average values by a specified value of 75% for B and 90% for the others. In order to trigger an alarm these conditions must be satisfied for two successive time periods and the alarm lasts for 5 y. Details of this algorithm have been given by Keilis-Borok (1996). Two examples of the application of this algorithm are given in Figure 14 for the 1989 Loma Prieta and the 1992 Landers earthquakes.

The earthquake catalog used in the *M8* studies is taken from the NEIC Global Hypocenter Database (GHDB, 1989), complete for $m \geq 5$ since 1963. Since the application of the *M8* algorithm requires at least 12 y of data to establish stable mean values, it can be applied continuously since 1975 and is continuously updated. The second algorithm is the *MSc* or Mendocino Scenario. This algorithm was designed to localize predictions within the relatively large circles used in the *M8* algorithm. It uses similar approaches to the *M8* but with smaller magnitude cut-offs. Details of this algorithm have been given by Keilis-Borok (1996).

The algorithms described above were developed using pattern recognition approaches. Although they have had demonstrated predictive successes (Kossobokov *et al.*, 1999; Rotwain and Novikova, 1999), their use remains quite controversial. The main difficulty is that, although success-to-failure ratios of predictions is quite high, the time and spatial windows of alarms are also quite high.

5.2 Seismic Activation

A second approach to intermediate-range earthquake forecasting is to consider whether a power-law increase in seismicity

FIGURE 14 Applications of the $M8$ algorithm to the $m = 7.1$ Loma Prieta earthquake (upper box) and the $m = 7.6$ Landers earthquake (lower box). In (a) the circular regions where TIPs have been declared are shown; in (b) the seismicity in the relevant region is shown and in (c) the values of the seven parameters N_1 , N_2 , L_1 , L_2 , Z_1 , Z_2 and B are shown along with the time interval of the TIP.

occurs prior to a major earthquake. We will refer to this as the seismic activation algorithm. This was first proposed by Bufe and Varnes (1993). They considered the cumulative amount of Benioff strain (square root of seismic energy) in a specified region. They showed that an accurate retrospective prediction of the Loma Prieta earthquake could be made assuming a power-law increase in Benioff strain prior to the earthquake.

Systematic increases in intermediate-level seismicity prior to a large earthquake have been proposed by several authors (Sykes and Jaumé, 1990; Knopoff *et al.*, 1996; Brehm and Braile, 1998, 1999; Jaumé and Sykes, 1999). A systematic study of the optimal spatial region and magnitude range to obtain the power-law seismic activation has been carried out by Bowman *et al.* (1998). Four examples of their results are given in Figure 15. Clear increases in seismic activity prior to the 1952 Kern County, 1983 Coalinga, 1989 Loma Prieta, and 1992 Landers earthquakes are illustrated. In each case data for the cumulative Benioff strain ε are compared with the empirical relation (solid line),

$$\varepsilon[t] = \varepsilon_0 - B(t_0 - t)^s \quad (22)$$

where t is the time measured forward from the previous characteristic earthquake, t_0 is the time interval between characteristic earthquakes, ε_0 is the cumulative Benioff strain when the characteristic earthquake occurs, and B and s are positive constants used to fit the data. The comparison with the Kern County data is made with $s = 0.30$, Coalinga $s = 0.18$, Loma Prieta $s = 0.28$, and Landers $s = 0.18$. For the 12 earthquakes studied by Bowman *et al.* (1998), it was found that $s = 0.26 \pm 0.15$.

There are clearly very strong similarities between the $M8$ and the seismic activation algorithms. Consider the Loma Prieta earthquake: the intermediate-sized events that led to the $M8$ TIP (Fig. 14) were the same events that give the increase in Benioff strain (Fig. 15). Both these approaches are based on the concept that correlation lengths increase before major earthquakes (Harris, 1998).

Bowman *et al.* (1998) also found ξ , the optimal radius (the correlation length) for the precursory activation. This optimal radius is given as a function of earthquake magnitude in Figure 16. The dependence on the square root of the rupture area is also shown. The radius over which activation occurs is about

FIGURE 15 Power-law increases in the cumulative Benioff strains prior to four major earthquakes in California (Bowman *et al.*, 1998). Data points are cumulative Benioff strains $\varepsilon[t]$ prior to each earthquake. Clear increases in seismic activity prior to the Kern County (21 July 1952), Coalinga (2 May 1983), Loma Prieta (18 October 1989), and Landers (28 June 1992) earthquakes are illustrated. In each of the four examples, the data have been correlated (solid lines) with the power-law relation given in Eq. (22). Dashed straight lines represent a best-fit constant rate of seismicity.

FIGURE 16 Optimum radius (correlation length) ξ for precursory seismic activation is given as a function of the square root of the rupture area $A_E^{1/2}$ and the magnitude m for 12 major earthquakes (Bowman *et al.*, 1998).

ten times the length of rupture $\xi \approx 10A_E^{1/2}$. Dobrovolsky *et al.* (1979) and Keilis-Borok and Kossobokov (1990) reported a similar scaling for the maximum distance between an earthquake and its precursors using pattern recognition techniques.

The observations of seismic activation given above are consistent with results obtained from studies of cellular-automata slider-block models using a mean-field approach (Rundle *et al.*, 1997, 1999, 2000). This approach involved concepts applied to equilibrium thermodynamics and the approach to a second-order phase transition through a spinoidal.

In the scaling associated with the approach to the critical point, the correlation length scales with the “rupture” length (square root of rupture area),

$$\xi \sim \langle A \rangle^{1/2} \quad (23)$$

as shown in Figure 16. In the vicinity of a critical point, it is appropriate to take (Stauffer and Aharony, 1992)

$$\xi \sim (t_0 - t)^{-1/2} \quad (24)$$

Combining Eqs. (23) and (24) we have

$$\langle A \rangle \sim (t_0 - t)^{-1} \quad (25)$$

We now use the results given above to obtain the power-law increase in Benioff strain prior to a characteristic earthquake. The mean seismic moment of the precursory earthquakes $\langle M \rangle$ is related to the mean of the slips $\langle \delta_s \rangle$ and the mean of the rupture areas $\langle A \rangle$ by

$$\langle M \rangle \sim \langle \delta_s \rangle \langle A \rangle \quad (26)$$

Under a wide variety of conditions it is found that the earthquake slip scales with the square root of the rupture area (Kanamori and Anderson, 1975),

$$\langle \delta_s \rangle \sim \langle A \rangle^{1/2} \quad (27)$$

so that we have

$$\langle M \rangle \sim \langle A \rangle^{3/2} \quad (28)$$

The rate at which precursory earthquakes generate moment, dM/dt , is given by

$$\frac{dM}{dt} = \langle M \rangle \frac{dN}{dt} \quad (29)$$

where dN/dt is the rate of occurrence of earthquakes. We assume that

$$\frac{dN}{dt} = \text{constant} \quad (30)$$

The rate at which precursory earthquakes occur is independent of time. This is consistent with observations of earthquakes. If there were a systematic increase in the rate of occurrence of precursory earthquakes prior to a main event, they could be used for earthquake prediction.

Substitution of Eqs. (25), (28), and (30) into Eq. (29) gives

$$\frac{dM}{dt} \sim A^{3/2} \quad (31)$$

Since the rate of change of Benioff strain is related to the rate of change of earthquake moment by

$$\frac{d\varepsilon}{dt} \sim \frac{dM^{1/2}}{dt} \sim \frac{1}{\langle M \rangle^{1/2}} \frac{dM}{dt} \quad (32)$$

substitution of Eqs. (25), (28), and (31) into Eq. (32) gives

$$\frac{d\varepsilon}{dt} \sim \langle A \rangle^{3/4} \sim \frac{1}{(t_0 - t)^{3/4}} \quad (33)$$

The cumulative Benioff strain as a function of time is given by

$$\begin{aligned} \varepsilon(t) &= \varepsilon_0 - \int_t^{\varepsilon_0} d\varepsilon = \varepsilon_0 - \int_t^{t_0} \frac{d\varepsilon}{dt} dt \\ &= \varepsilon_0 - C \int_t^{t_0} \frac{dt}{(t_0 - t)^{3/4}} = \varepsilon_0 - B(t_0 - t)^{1/4} \end{aligned} \quad (34)$$

where C and B are constants. Comparing Eqs. (34) and (22), we see that the two equations are identical if we take $s = 0.25$. For the 12 earthquakes studied by Bowman *et al.* (1998), $\bar{s} = 0.26 \pm 0.15$. Thus excellent agreement is found between the critical point theory and actual earthquake data on seismic activation.

5.3 Log-Periodic Behavior

It has also been suggested that precursory seismic activity exhibits log-periodic behavior. Sornette and Sammis (1995) and Saleur *et al.* (1996) have used a generalized log-periodic relation to fit the strain accumulation data of Bufe and Varnes (1993) for the Loma Prieta earthquake. The data appear to exhibit a series of log-periodic fluctuations. An important question is whether this type of strain accumulation data can be used to predict earthquakes. Sornette and Sammis (1995) used the log-periodic fit to the data available prior to a cut-off date to predict when an earthquake would be expected. The predictions became increasingly accurate as the cut-off times approached the date of the Loma Prieta earthquake, 17 October 1989. Although the ability to make this retrospective prediction is encouraging, it remains to be demonstrated that this technique can be used successfully to predict earthquakes. A general discussion of log-periodicity has been given by Sornette (1998).

Another intriguing example of log-periodic behavior prior to an earthquake has been given by Johansen *et al.* (1996). These authors considered chlorine ion concentrations in bottled water taken from two 100 m deep wells located 20 km from the epicenter of the $m = 6.9$ Kobe (Japan) earthquake of 17 January 1995, prior to the earthquake. Again, a log-periodic fit to the data was found.

6. Implications

It is instructive to make comparisons between the behavior of the Earth's atmosphere and the behavior of the Earth's crust. Both are extremely complex on a very wide range of scales. From a practical point of view it is impossible, in either case, to make a sufficient number of measurements to fully specify the problem. Both have significant stochastic components. Both are undoubtedly chaotic. But what are the relative roles of stochastic versus chaotic behavior?

Massive numerical simulations are routinely used to forecast the weather. In many cases, they are quite accurate on time scales of 24–48 h, but on the scale of weeks they are of little value. The motions of the storm systems are relatively stable considering the complexity involved. In many cases the paths of major storms such as hurricanes can be predicted with considerable accuracy, but in other cases there are major uncertainties. One approach to establishing whether a particular predicted storm path is stable is to apply alternative numerical models. If the models all predict essentially the same path, then the path is taken to be stable. If the models predict radically different paths, then any forecast is considered to be suspect. This is also the way classical chaotic systems such as the Lorenz attractor behave. At many points on the evolving trajectory there is relatively little sensitivity to small perturbations, and at other points there is extreme sensitivity.

But what about the Earth's crust? Forecasting or predicting an earthquake is quite different from forecasting the path and intensity of a hurricane. The hurricane exists, but the earthquake does not exist until it happens. Geller *et al.* (1997) have argued, on the basis of the chaotic behavior of the Earth's crust, that "earthquakes cannot be predicted." This is certainly true in the sense that the exact time of occurrence of an earthquake cannot be predicted. But probabilistic forecasts of hurricane paths with a most probable path are routinely made and their use is of great value in terms of requiring evacuations and other precautions.

The essential question concerning earthquakes is whether similar, useful, probabilistic forecasts can be made. In fact, this is already being done in terms of hazard assessments. Certainly earthquakes do not occur randomly on the surface of the Earth. Also, the occurrence of large earthquakes can be associated with the occurrence of small earthquakes. In Section 4, we discussed a systematic approach to hazard assessment based on concepts of complexity.

In Section 5 we addressed the more intriguing question, whether useful forecasts of the temporal occurrence of earthquakes can be made, and in particular whether useful forecasts can be made based on concepts of complexity. In our opinion no definitive answer can be made at this time. We discussed two approaches to intermediate-range (month to several years) forecasting. There were a number of positive aspects to these approaches, but there is certainly no general consensus that useful intermediate-range forecasts can be made.

Physics of Earthquakes

Roman Teisseyre and Eugeniusz Majewski

Institute of Geophysics, Polish Academy of Sciences, Warsaw, Poland

1. Introduction

The problem of earthquake processes is considered here at two levels. We start with an overview of the classical macroscopic approach to faulting processes, which is commonly used by seismologists. Next, we proceed with the microphysics of fracture in minerals and rocks. In the microscopic approach we emphasize the irreversible deformations resulting from dislocations, microcracks, and other microscopic defects. The microscopic formulation is finally applied in a qualitative description of earthquake processes. Some recent results of earthquake thermodynamics are also briefly reviewed. Theoretical results for the strain, stress, earthquake magnitude, seismic moment, and entropy change during an earthquake process are presented.

This chapter is organized as follows. In Section 2 there is a brief discussion of current knowledge about the classical macroscopic approach to fault zone dynamics, pointing out the advantages and disadvantages of this formulation. This is not intended to be a comprehensive review, as several of these have appeared in recent years. In Section 3 a microscopic approach to fracturing is reviewed, based mainly on microscopic fracture statistics. This is followed in Section 4 by a discussion of an elastic continuum medium with a defect content. Here the relevant theoretical mechanisms of microscopic deformation are described. Section 5 deals with earthquake thermodynamics. Finally, a qualitative discussion of various aspects of the earthquake models described is presented, and it is shown how physical effects such as self-organized criticality, chaos, and complexity arise. Some detailed considerations and further explanations are to be found in the Appendices on the attached Handbook CD.

2. The Macroscopic Approach to Fault Zone Dynamics

2.1 General Considerations

The seismological observations and the laboratory experimental data on fracturing processes are well described by the

instantaneous development of slip on a fault (instantaneous crack propagation). The appropriate solutions of the elastodynamic equation $\text{div } \mathbf{S}(\mathbf{u}) = \rho \ddot{\mathbf{u}}$ (where the stress tensor $\mathbf{S}$ is related to the displacement vector $\mathbf{u}$ by the constitutive law, body forces are neglected, and ρ is the density, constant within a fault zone) can be calculated with the boundary integral formulation on a fault surface. At each fault element, stress is continuous, while displacements can be opposite on the different sides of surface element during slip. It is assumed, that the applied stresses on the fault follow the values of dynamic friction when a slip nucleates; and further that friction obeys some weakening law (a source of instabilities) as determined from observations and experimental data. The singularities appearing in a crack field can be eliminated by defining a *cohesive force*, which acts only inside the crack near its tip (see Appendix I).

For a review of problems related to a crack theory, see Rice (1968a). A central problem of fracture mechanics is the knowledge of the stress and deformation fields near the advancing crack as its active plastic zone precedes the propagating crack (fracture toughness; Ponte Castañeda, 1987). In this context it is worth mentioning the phenomenon of stress corrosion which is related to the action of some chemical agents at a crack tip; the crack fracturing process becomes accelerated; and the stress intensity/crack velocity data can be described in the form of a power law (Atkinson and Meredith, 1987).

2.2 Instabilities and Friction Weakening Constitutive Laws

For a review of the instability problem, see Giovanola and Finnie (1984). The J -integral (Rice, 1968b) describes a potential energy variation by crack extension; its behavior relates to instabilities in crack motion and serves to estimate work done in the plastic process zone. Another source of instability may be due to pore fluid pressure and fluid percolation (formation of connectivity between voids). The instabilities can arise due to a dissipation of frictional heat (Lachenbruch, 1980; Shaw, 1995). Frictional sliding can be represented as a thermally activated creep process (Stesky, 1975). A general instability

criterion states that instability in a nucleation volume occurs at a negative product of the stress rate and the sum of elastic and plastic strain rates $\dot{S}(\dot{\epsilon} + \dot{\epsilon})$ (see Hill, 1958).

Considering slip propagation along a fault, the frictional instabilities can be described by the rate and state formalism (Linker and Dieterich, 1992):

$$\mu = \mu_0 + a \ln\left(\frac{V}{V_0}\right) + b \ln\left(\frac{\psi}{\psi_0}\right), \quad \frac{\partial \psi}{\partial t} = \frac{1}{t_0} - \frac{V\psi}{D_c} \quad (1)$$

where μ is the coefficient of friction; V is the macroscopic frictional slip velocity, ψ is the state variable; μ_0 , a , b , and ψ_0 are constants; V_0 is a reference velocity; t_0 is a reference time; and D_c is a critical displacement on a fault (see Appendix I).

Ohnaka in a series of high-resolution laboratory experiments (Ohnaka, 1998; Ohnaka and Shen, 1999) demonstrated that the constitutive law for shear rupture should be primarily slip-dependent.

2.3 Elastodynamic Solutions

Good reviews of works on this topic are given by Aki and Richards (1980), Rice (1980), Ben-Menachem and Singh (1981), and Scholz (1990). Among more recent papers, we mention the analytic solutions for antiplane slip given by Campillo and Ionescu (1997). Their eigenvalue analysis associated the positive eigenvalues with the dominant part of the solution, which on the fault exhibits an exponential growth in time. This dominant part also decreases exponentially away from the fault in the same way as the eigenfunctions do. The other part of the solution associated with negative eigenvalues, the “wave part,” rapidly becomes negligible when instability develops. This solution seems important in showing that the elastodynamic equation can be split into a slip and a wave part (see Section 4).

2.4 Earthquake Cycles on Tectonic Planes

Large earthquakes occur repeatedly along large-scale faults. An earthquake cycle includes tectonic stress accumulation, fracture nucleation, propagation, arrest, and fault-healing. Problems of such cycles can be approached by studying the constitutive rate- and state-dependent laws determining the fracturing, fracture nucleation, and healing conditions (Ben-Zion and Rice, 1995; Sleep, 1995). Matsu'ura (1995) considered a transition process from nucleation to dynamic rupture. Rundle (1988) introduced the idea that an earthquake represents a fluctuation about the long-term motion of the plates: the fluctuation hypothesis. Fault interactions in recurrent earthquake cycles have been studied by Senatorski (1995). The suggestion that strong heterogeneities in a fault zone act as barriers affecting seismicity and rupture arrest has been considered by Das and Aki (1977), Kanamori and Stewart (1978), Aki (1984), Rybicki and Yamashita (1998), and Yamashita (1999).

3. The Microscopic Approach to Fracturing

3.1 Microscopic Mechanisms

Depending on stress level, confining pressure, temperature, fluid content, and rock properties, the following different modes can accommodate the deformation: elastic distortion, plastic flow, phase changes, nucleation and growth of ductile microvoids, nucleation and growth of brittle microcracks, and nucleation and growth of shear instabilities (see Curran *et al.*, 1987). Fracture proceeds through the nucleation, growth, coalescence, and fragmentation phases. In the microfracturing processes the microcracks and voids (in which material bonds are broken) play the role of the main objects. However, considering more elementary objects of preparatory processes leading to fracturing, we will refer to dislocations and vacancies (in which bonds are unbroken and material consistency is preserved).

3.2 Nucleation and Growth

The noninteracting voids and cracks can be described according to experimental evidence (Curran *et al.*, 1987) by the following distribution:

$$N(R) = N_0 \exp\left(-\frac{R}{R_0}\right) \quad (2)$$

where R is the size of the flaw, N is the number of flaws greater than or equal to R per unit volume, and R_0 is the characteristic size, specific for material and physical conditions. At high crack density, cracks are no longer independent objects. The evidence related to seismic events (Turcotte, 1986) points to a distribution relation of the fractal type:

$$N(R) \propto R^{-D} \quad (3)$$

This is a scale-invariant distribution law (Turcotte, 1992). Czechowski (1991) obtained this type of distribution using the kinetic theory of crack fusion (coagulation theory), finding a transition from the exponential relation toward a power-law relation [Eq. (3)] with $D = 3/2$.

For the equilibrium between stable and activated bonds, Boltzmann statistics can be applied (Curran *et al.*, 1987); for the breaking and healing of bonds, we can put (see Appendix II)

$$\dot{\eta} = \frac{\eta kT}{h} \exp\left(-\frac{\Delta G \mp W}{kT}\right) \quad (4)$$

where η is the number of bonds per unit area, ΔG is the energy difference between the activated and broken bonds, h is the Planck constant, and $W = S \delta \lambda / \eta$ is the external work required to break a bond (S is the stress field; $\delta \lambda$ is the stretching of a bond before it breaks; λ is the bond length); the upper sign

is for bond breaking and the lower one for healing. The net rate of bond fracture is given by the difference; putting the number of bonds per unit volume $N = \eta/\lambda$, and introducing the bond breaking strain $\varepsilon = \delta\lambda/\lambda$, we get the rate of bond breaking per unit of microscopic flaw containing n bonds:

$$\dot{N} = \frac{S_s \varepsilon}{nh} \exp\left(\frac{S - S_f}{S_s}\right) \quad (5)$$

Two critical stress thresholds appear here: $S_s = NnkT/\varepsilon$ for the slow fracturing process, and $S_f = Nn \Delta/\varepsilon$ for the fast fracturing process (Curran *et al.*, 1987).

3.3 Plastic Failure

Shear instabilities lead to nucleation of shear bands; along shear planes the dislocation arrays are formed. The Orowan equation connects the plastic strain rate $\dot{\varepsilon}$ with the number of shear bands $\bar{N}$ intersecting a unit of surface and the average band velocity $\bar{V}$:

$$\dot{\varepsilon} = \bar{N} \bar{V} B \quad (6)$$

where B relates here to the jog accommodated by the band (it corresponds to a Burgers vector that had intersected the band).

Creep phenomena are regarded as thermally activated phenomena—Arrhenius's law; the Andrade law of creep gives a good representation of the experimental data in relation to stresses S . Both laws can be combined as (see Appendix II)

$$\dot{\varepsilon} = \dot{\varepsilon}_0 t^m S^m \exp(-\Delta H/RT) \quad (7)$$

where for transient creep $m < 0$ and for steady-state creep $m = 0$, while for tertiary creep growth $m > 0$; ΔH is the activation enthalpy.

3.4 Coalescence Processes and Microcrack Formation

A further phase of shear deformation is based on the formation of slip bands, grain boundary sliding, dislocation pile-ups, dislocation-to-crack transition, and microcrack formation. The formation of dislocation arrays and the interaction between the groups of dislocations of opposite signs lead to the coalescence processes (see Section 4): microcracks nucleate and shear slip-bands merge. Stroh (1957) considered the energy balance related to the process of crack formation at the zone of stress concentration at the tip of the dislocation array; the “dislocation-to-crack” process has been considered by Teisseyre (1969) and Dmowska *et al.* (1972) as one of possible energy release processes. The premonitory and rebound theory (Teisseyre, 1995) describes the evolution of internal stress (stress concentration) due to dislocation pile-ups and further to their coalescence with the opposite dislocation arrays.

To continuum theories of fracturing we also add the crack fusion theories; the concept of crack fusion as an earthquake

mechanism was investigated by Newman and Knopoff (1982, 1990). Percolation theories (e.g., Chelidze, 1982; Turcotte, 1992), following the original considerations on electric resistivity, use a network of sites with bonds between them. A critical process, like fracture, takes place when a cluster of the sites with broken bonds emerges.

4. Continuum with Defect Content

4.1 Equation of Motion for Elastodynamics with Defect Impact

In the elastodynamic solutions describing slip propagation along a fault, the condition for stresses at infinitely remote boundaries specifies the external stress load. A boundary condition on a fault incorporates the possibility of displacement discontinuity—a slip. This slip, related to the sought elastodynamic solutions, obeys the friction constitutive law, determined from the experimental data. This allows a successful use of the elastodynamic equations, in spite of the fact that these equations do not theoretically apply to an elastic continuum that includes any distribution of defects as objects with their own stress field. In an elastic continuum with defects (more exactly, a continuum with a continuous distribution of the self-strain nuclei: thermal nuclei, dislocations, and disclinations), we have to consider the elastic $\mathbf{E}$, $\mathbf{S}$ and self parts $\mathbf{E}^S$, $\mathbf{S}^S$ of the total strain and stress fields $\mathbf{E}^T$, $\mathbf{S}^T$, subjected to the same type of stress-strain constitutive relation:

$$\mathbf{E}^T = \mathbf{E} + \mathbf{E}^S, \quad \mathbf{S}^T = \mathbf{S} + \mathbf{S}^S, \quad \mathbf{S} = \lambda \text{tr}(\mathbf{E})\mathbf{1} + 2\mu\mathbf{E} \quad (8)$$

where $\text{tr}(\dots)$ means tensor contraction, and λ and μ are Lamé material constants.

We obtain the motion equation in an elastic continuum with defects (see Appendix III):

$$\text{div } \mathbf{S} = \rho \frac{d}{dt} \mathbf{v}, \quad \text{div } \mathbf{S} = \rho \frac{d^2}{dt^2} \mathbf{u} - \rho \frac{d}{dt} \mathbf{v}^s \quad (9)$$

where ρ is a constant, $\mathbf{u}$ is the displacement, $\mathbf{v}$ is the velocity, and $\mathbf{v}^s$ is the self (plastic) velocity.

We could add that the commonly used stick-slip model, together with the elastodynamic equation, neglects the self-stress fields from objects on a fault plane. The self (plastic) parts are crucial as the self-stresses in an interaction with elastic stresses govern a slip evolution process. There exist direct relations between dislocations and stresses in two dimensions (Teisseyre, 1997; Appendix III); for the antiplane (screw dislocations) and in-plane (edge dislocations) we obtain

$$\alpha - \frac{1}{2} \text{tr}(\alpha)\mathbf{1} = \frac{1}{2\mu} \text{curl} \left(\mathbf{S} - \frac{\nu}{1+\nu} \text{tr}(\mathbf{S})\mathbf{1} \right), \quad \alpha = -\text{curl } \beta^s \quad (10)$$

where α is the dislocation density defined in relation to the plastic distortion β^s (Kröner, 1958).

Assuming after Kossecka and DeWitt (1977) that the self (plastic) velocities $\mathbf{v}^s$ relate to motion of dislocations, we can consider the dislocation flow current $\mathbf{J}$ as the difference between the time and space derivatives of plastic distortion and plastic velocity, or equivalently, as the vector product of the dislocation density and its velocity $\mathbf{V}$:

$$\mathbf{J} = \frac{\partial}{\partial t} \beta^s - \frac{\partial}{\partial \mathbf{x}} \mathbf{v}^s, \quad \mathbf{J} = c\alpha \times \mathbf{V}, \quad \frac{\partial \alpha}{\partial t} + \nabla \times \mathbf{J} = \Pi \quad (11)$$

where Π is the source/sink function describing the interaction between the dislocations of the opposite signs (Teisseyre and Nagahama, 1998), and c is the shear wave velocity.

From Eqs. (10) and (11) we can derive the expression for plastic velocity $\mathbf{v}^s$; after differentiation and symmetrization of the motion equation [Eq. (9)], we come to the following form (for details, see Appendix III):

$$(\nabla \operatorname{div} \mathbf{S})_{\text{sym}} = \frac{\rho}{\mu} \left[\ddot{\mathbf{S}} - \frac{\lambda}{3\lambda + 2\mu} \operatorname{tr}(\ddot{\mathbf{S}}) \mathbf{1} \right] + \rho c \frac{d}{dt} (\alpha \times \mathbf{V})_{\text{sym}} \quad (12)$$

where “sym” means symmetrization procedure.

4.2 Splitting the Stress Motion Equations into Wave and Fault-Related Parts

Taking the antiplane problem (function independent of z) and assuming that the dislocations move only in the x direction, we obtain the motion equations (Teisseyre and Yamashita, 1999):

$$\frac{\partial^2 S_{zx}}{\partial x \partial y} + \frac{\partial^2 S_{zy}}{\partial y^2} - \frac{1}{c^2} \frac{\partial^2 S_{zy}}{\partial t^2} = \frac{\mu}{c} \frac{\partial}{\partial t} (\alpha V) - F, \quad (13)$$

$$\frac{\partial^2 S_{zx}}{\partial x^2} + \frac{\partial^2 S_{zy}}{\partial x \partial y} - \frac{1}{c^2} \frac{\partial^2 S_{zx}}{\partial t^2} = 0$$

An elastic stress field $\mathbf{S}$ can now be presented as the difference $\mathbf{S}^T - \mathbf{S}^S$ between the total $\mathbf{S}^T$ field and the self $\mathbf{S}^S$ stress part, which is assumed to rapidly decrease away from the fault plane. We can identify these parts with a fault-related field $S_{zi}^S = \tilde{S}_{zi}$ ($i = x, y$) and a radiation field $S_{zi}^T = \tilde{S}_{zi}$ (total stresses are related to a displacement field).

On the fault plane (x, t) the fracturing processes cause the stress to change, while a seismic wave radiation will be observed in the considered (x, y, t) domain. The equation of motion [Eq. (13)] now splits into two parts. The first relates to a fault (x, t) domain):

$$\frac{1}{c^2} \frac{\partial^2}{\partial t^2} \tilde{S}_{zy} - \frac{1}{c} \frac{\partial}{\partial t} \left[V \frac{\partial}{\partial x} \tilde{S}_{zy} \right] = F, \quad \frac{1}{c^2} \frac{\partial^2}{\partial t^2} \tilde{S}_{zx} - \frac{\partial^2}{\partial x^2} \tilde{S}_{zx} = 0 \quad (14)$$

Here $\bar{\alpha} = -(1/\mu) \partial \tilde{S}_{zy} / \partial x$ relates to a slip δ on a fault $\bar{\alpha} = (1/\Lambda) \nabla \delta$ (with some characteristic length Λ). For the $\tilde{S}_{zx}$ component we can put $\tilde{S}_{zx} = 0$, as it is subject to the homogeneous equation. For $\tilde{S}_{zy}$ we may solve the equation (for details, see Appendix III)

$$\frac{1}{c^2} \frac{\partial^2}{\partial t^2} \tilde{S}_{zy} + \frac{\mu}{cR} \operatorname{sgn} \bar{\alpha} \frac{\partial}{\partial t} \frac{\partial}{\partial x} \left[\frac{\tilde{S}_{zy} - R}{|R^2 + (\tilde{S}_{zy} - R)^2|^{1/2}} \frac{\partial \tilde{S}_{zy}}{\partial x} \right] = \frac{\partial}{\partial t} \Pi \quad (15)$$

Returning to the motion equation [Eq. (13)], we obtain for $\tilde{S}(x, y, t)$ the homogeneous wave equations; assuming that the elastic stress field $\mathbf{S} = \tilde{\mathbf{S}} - \tilde{\mathbf{S}}$ on a fault is small ($\mathbf{S} \ll \tilde{\mathbf{S}}$) we have the boundary condition $\tilde{S}_{zy}(x, y = 0, t) = \tilde{S}_{zy}(x, t)$. We put $\tilde{S}_{zx}^0 = 0$ as $\tilde{S}_{zx} = 0$.

For the dislocation stress resistance and for the friction on a fault, we may take the weakening constitutive laws introducing the instabilities in a preseismic phase (motion of dislocations), in a slip nucleation phase, and in a slip propagation phase. We note now that instead of the instability sources introduced by the weakening laws for all these phases, we may take the adequate source/sink functions Π (discussed by Teisseyre and Nagahama, 1998). The numerical simulations, performed according to Eq. (14), show some instabilities that might be identified with seismic events (Teisseyre, 1997).

5. Earthquake Thermodynamics

5.1 Thermodynamic Relationship

The equilibrium states are characterized by the extreme values of some thermodynamic functions (Majewski, 1993):

$$H = U - W, \quad F = U - T\tilde{S}, \quad G = H - T, \quad \text{where } dU + dW = dQ + S dE \quad (16)$$

where H is the enthalpy, F is the Helmholtz free energy, G is the Gibbs free energy, T is the absolute temperature, and $\tilde{S}$ is the entropy, and where internal energy U enters into the first law of thermodynamics; work done W relates here to shear load S and strain E .

Rice (1978) has estimated entropy production due to a stationary crack growth. Rundle (1989) reconsidered this question using a statistical approach (transitions to slip states approach a minimum of Helmholtz free energy). In a damage rheology model, Lyakhovsky *et al.* (1997a,b) applied a general thermodynamic formulation to account for viscous relaxation and evolution of damage with material degradation and healing. In a rate-dependent formulation, Majewski and Teisseyre (1998) considered anticrack-associated faulting and superplastic flow in deep subduction zones.

5.2 Dislocation Superlattice

Basic thermodynamic relations for line defects (dislocations and vacant dislocations) are derived under the assumption of a dense network of defects forming a kind of superlattice (Majewski and Teisseyre, 1997; Teisseyre and Majewski, 2001). Considering a system that contains a superlattice of dislocations and vacant dislocations with a superlattice parameter Λ ($\Lambda \gg \lambda$, where λ relates to a crystal lattice), we associate the thermodynamic functions with the vacant dislocations; the Gibbs free energy can have a minimum corresponding to the equilibrium concentration of the vacant dislocations (for details, see Appendix IV).

In a real body with n dislocations we may add to it the other $\hat{n}$ vacant dislocations; a whole set $N = n + \hat{n}$ corresponds to a superlattice; for the equilibrium state of density of dislocations and vacant dislocations we obtain ($\Delta s = \Lambda^2$):

$$\alpha = \frac{b}{\Lambda^2} \left[1 - \exp\left(-\frac{\hat{g}^f}{kT}\right) \right], \quad \hat{\alpha} = \frac{b}{\Lambda^2} \exp\left(-\frac{\hat{g}^f}{kT}\right) \quad (17)$$

where $\hat{g}^f$ is the formation energy of a vacant dislocation.

For the vacant dislocations, a change in the Gibbs energy depends on the stress level and resistance stress ($\partial \hat{G} / \partial \hat{n} = \hat{g}^f = (S - R)b\lambda^2$; Kocks *et al.*, 1975). Similarly to the $CB\Omega$ model introduced by Varotsos and Alexopoulos (1986) for point defects, we postulate the approximate value for the formation energy, independent of stresses (C is a constant):

$$\begin{aligned} \hat{g}^f &= C\mu\lambda\Lambda^2, & \hat{n}^{\text{eq}} &= N \exp\left(-\frac{C\mu\lambda\Lambda^2}{kT}\right), \\ \hat{\alpha} &= \frac{b}{\Lambda^2} \exp\left(-\frac{C\mu\lambda\Lambda^2}{kT}\right) \end{aligned} \quad (18)$$

For the equilibrium state under a constant local shear S and temperature T , the Gibbs energy can reach its minimum. In a similar way, we can estimate the entropy changes.

5.3 Earthquake Thermodynamics

We approach the problem of earthquake thermodynamics with the principle of the local equilibrium condition; we assume that the state reached after a seismic event is near to an equilibrium distribution of vacant dislocations. However, the state before an earthquake cannot be described by a similar assumption; we may assume that in a zone of earthquake formation we have a very dense distribution of dislocations, forming arrays along the slip shear planes, while the number of vacant dislocations is near zero. However, we might be, formally, close to equilibrium when assuming that the Λ undergoes the changes; at least on the shear plane, an excess of dislocations destroys the Λ structure and the superlattice approaches the λ structure on slip planes (only).

Accordingly, we assume that before an earthquake a superlattice is almost completely filled with dislocations

($n \approx N$ and $\hat{n} \approx 0$), and we will also assume that only along the glide planes is the Λ structure destroyed by formation of the dislocation arrays. The maximum number of dislocations in arrays could reach the value (Λ/λ) per distance Λ ; the maximum value of the Burgers vector becomes $b = \lambda(\Lambda/\lambda) = \Lambda$. After an earthquake, $\hat{n}$ will increase by $\Delta\hat{n}(\Lambda/\lambda)$ to nearly its equilibrium value [Eq. (18)]. The total number of line defects $N = n + \hat{n}$ can be estimated as the ratio of an earthquake source volume $\pi R^2 H$ (R is the seismic radius; H is the source thickness) and the parallelepiped volume $\lambda^2 \Lambda$. Using the expression for a change in the Burgers vector and in the free energy values, we arrive at the formulae for the released energies, seismic moment, and entropy (for details, see Appendix IV).

6. Conclusions

The state of the art of the physics of earthquakes as well as of microscopic fracturing is reviewed. Our approach is to trace the development of the deformation from its roots at the atomic level to its macroscopic manifestation in earthquake faulting. Many examples of current works on the interplay between macroscopic rock fracture and microscopic line defect interactions in some earthquake processes are presented here. Models of crack nucleation are based on the hierarchical structure of the formation of slip-bands, grain boundary sliding, dislocation pile-ups, dislocation-to-crack transition, and microcrack formation. The formation of dislocation arrays and interactions between the groups of dislocations of opposite signs lead to the coalescence processes: microcracks nucleate and shear slip-bands merge. Many of these defects have been identified at the atomic level with the aid of measurements and microscopic observations.

Even with such a detailed understanding of the defects, it is still not possible to treat the full complexity of the problems encountered with the help of classical theories. As described by Anderson (1991), complementary views can be provided by theories of complexity and emergent phenomena, which include chaos and self-organized criticality. Self-organization and complexity theory were outlined in famous books by Nicolis and Prigogine (1977, 1989). Several aspects of complexity theory are beginning to have a major impact on the understanding of earthquake faulting and rock fracture processes, as discussed in Chapter 14 by Turcotte and Malamud.

In the last ten years it has become increasingly evident that there exist numerous examples of geophysical systems where spatial, temporal, or spatiotemporal structures arise out of chaotic states. These phenomena occur in systems in which there is an exchange of energy and matter with the environment, and these structures develop spontaneously and are self-organizing. In addition to thermodynamic instabilities, in such systems one can expect three stages of evolution: organization, self-organization, and chaos (Majewski, 1993). The transitions

between these stages are the subject of study in the new interdisciplinary science named *synergetics*, first introduced by Haken (1978). It was shown in synergetics that numerous systems display striking similarities in their behavior when passing from the disordered to the ordered state and vice versa. This indicates that the functioning of these systems obeys the same general principles.

Recent years have brought a revival of work on self-organized space–time structures and criticality in earthquakes (Bak and Tang, 1989; Sornette and Sornette, 1989; Ito and Matsuzaki, 1990), which have been a source of fascination since their discovery. Preliminary investigation of the phenomenology of nonlinear phase transitions is also quite encouraging. However, it is clear that we have only begun to explore the structure of these new nonlinear theories (e.g., Lomnitz-Adler, 1993; Fisher *et al.*, 1997; Dahmen *et al.*, 1998). If history is a reliable guide to the future, then, as our understanding of these theories improves, new domains of nonlinear physics and new questions will appear.

Acknowledgments

This chapter was greatly improved by the remarks proposed by the reviewers: D.L. Turcotte, Y. Ben-Zion, and an anonymous reviewer; the authors express their thanks.

Probabilistic Approach to Inverse Problems

Klaus Mosegaard

Niels Bohr Institute, Copenhagen, Denmark

Albert Tarantola

Institut de Physique du Globe, Paris, France

1. Introduction

In ‘inverse problems’ data from indirect measurements are used to estimate unknown parameters of physical systems. Uncertain data (possibly vague) prior information on model parameters, and a physical theory relating the model parameters to the observations are the fundamental elements of any inverse problem. Using concepts from probability theory, a consistent formulation of inverse problems can be made, and, while the most general solution of the inverse problem requires extensive use of Monte Carlo methods, special hypotheses (e.g., Gaussian uncertainties) allow, in some cases, an analytical solution to part of the problem (e.g., using the method of least squares).

1.1 General Comments

Given a physical system, the ‘forward’ or ‘direct’ problem consists, by definition, in using a physical theory to predict the outcome of possible experiments. In classical physics this problem has a unique solution. For instance, given a seismic model of the whole Earth (elastic constants, attenuation, etc. at every point inside the Earth) and given a model of a seismic source, we can use current seismological theories to predict which seismograms should be observed at given locations at the Earth’s surface.

The ‘inverse problem’ arises when we do not have a good model of the Earth, or a good model of the seismic source, but we have a set of seismograms, and we wish to use these observations to infer the internal Earth structure or a model of the source (typically we try to infer both).

There are many reasons that make the inverse problem underdetermined (nonunique). In the seismic example, two different Earth models may predict the same seismograms,¹ the finite bandwidth of our data will never allow us to resolve

very small features of the Earth model, and there are always experimental uncertainties that allow different models to be ‘acceptable.’

The name ‘inverse problem’ is widely used. The authors of this chapter only like this name moderately, as we see the problem more as a problem of ‘conjunction of states of information’ (theoretical, experimental, and prior information). In fact, the equations used below have a range of applicability well beyond ‘inverse problems’: they can be used, for instance, to predict the values of observations in a realistic situation where the parameters describing the Earth model are not ‘given’ but only known approximately.

We take here a probabilistic point of view. The axioms of probability theory apply to different situations. One is the traditional statistical analysis of random phenomena, another one is the description of (more or less) subjective states of information on a system. For instance, estimation of the uncertainties attached to any measurement usually involves both uses of probability theory: Some uncertainties contributing to the total uncertainty are estimated using statistics, while some other uncertainties are estimated using informed scientific judgment about the quality of an instrument, about effects not explicitly taken into account, etc. The International Organization for Standardization (ISO) in *Guide to the Expression of Uncertainty in Measurement* (1993), recommends that the uncertainties evaluated by statistical methods are named ‘type A’ uncertainties, and those evaluated by other means (for instance, using Bayesian arguments) be named ‘type B’ uncertainties. It also recommends that former classifications, for instance into ‘random’ and ‘systematic uncertainties,’ should be avoided. In the present text, we accept ISO’s basic point of view, and extend it by downplaying the role assigned by ISO to the particular Gaussian model for uncertainties (see Section 4.3) and by not assuming that the uncertainties are ‘small.’

In fact, we like to think of an ‘inverse’ problem as merely a ‘measurement.’ A measurement that can be quite complex, but the basic principles and the basic equations to be used are the same for a relatively complex ‘inverse problem’ as for a relatively simple ‘measurement.’

We do not normally use, in this text, the term ‘random variable,’ as we assume that we have probability distributions over ‘physical quantities.’ This is a small shift in terminology that we hope will not disorient the reader.

An important theme of this paper is *invariant formulation* of inverse problems, in the sense that solutions obtained using different, equivalent, sets of parameters should be consistent, i.e., probability densities obtained as the solution of an inverse problem, using two different set of parameters, should be related through the well-known rule of multiplication by the Jacobian of the transformation.

This chapter is organized as follows. After a brief historical review of inverse problem theory, with special emphasis on seismology, we give a short introduction to probability theory. In addition to being a tutorial, this introduction also aims at fixing a serious problem of classical probability, namely the noninvariant definition of conditional probability. This problem, which materializes in the so-called Borel paradox, has profound consequences for inverse problem theory.

A probabilistic formulation of inverse theory for general inverse problems (usually called ‘nonlinear inverse problems’) is not complete without the use of Monte Carlo methods. Section 3 is an introduction to the most versatile of these methods, the Metropolis sampler. Apart from being versatile, it also turns out to be the most natural method for implementing our probabilistic approach.

In Sections 4, 5, and 6 time has come for applying probability theory and Monte Carlo methods to inverse problems. All the steps of a careful probabilistic formulations are described, including parametrization, prior information over the parameters, and experimental uncertainties. The hitherto overlooked problem of uncertain physical laws (‘forward relations’) is given special attention in this text, and it is shown how this problem is profoundly linked to the resolution of the Borel paradox.

Section 7 treats the special case of the mildly nonlinear inverse problems, where deterministic (non-Monte Carlo) methods can be employed. In this section, invariant forms of classical inversion formulas are given.

1.2 Brief Historical Review

For a long time scientists have estimated parameters using optimization techniques. Laplace explicitly stated the least absolute values criterion. This, and the least-squares criterion were later popularized by Gauss (1809). While Laplace and Gauss were mainly interested in overdetermined problems, Hadamard (1902, 1932) introduced the notion of an ‘ill-posed problem,’ which can be viewed in many cases as an underdetermined problem.

The late 1960s and early 1970s were a golden age for the theory of inverse problems. In this period the first uses of Monte Carlo theory to obtain Earth models were made by Keilis-Borok and Yanovskaya (1967) and by Press (1968). At about the same time, Backus and Gilbert, and Backus alone, in the years 1967–1970, made original contributions to the theory of inverse problems, focusing on the problem of obtaining an unknown *function* from discrete data. Although the resulting mathematical theory is elegant, its initial predominance over the more ‘brute force’ (but more powerful) Monte Carlo theory was only possible due to the quite limited capacities of the computers at that time. It is our feeling that Monte Carlo methods will play a more important role in the future (and this is the reason why we put emphasis on these methods in this chapter). An investigation of the connection between analog models, discrete models, and Monte Carlo models can be found in a paper by Kennett and Nolet (1978).

Important developments of inverse theory in the fertile period around 1970 were also made by Wiggins (1969), with his method of suppressing ‘small eigenvalues,’ and by Franklin (1970) by introducing the right mathematical setting for the Gaussian, functional (i.e., infinite dimensional) inverse problem (see also Lehtinen *et al.*, 1989). Other important papers from the period are those of Gilbert (1971) and Wiggins (1972).

A reference that may interest some readers is Parzen *et al.* (1998), where the probabilistic approach of Akaike is described.

To the ‘regularizing techniques’ of Tikhonov (1963), Levenberg (1944), and Marquardt (1970), we prefer, in this chapter, the approach where the a priori information is used explicitly.

For seismologists, the first bona fide solution of an inverse problem was the estimation of the hypocenter coordinates of an earthquake using the ‘Geiger method’ (Geiger, 1910), which present-day computers have made practical. In fact, seismologists have been the originators of the theory of inverse problems (for data interpretation), and this is because the problem of understanding the structure of the Earth’s interior using only surface data is a difficult one.

3-D tomography of the Earth, using travel times of seismic waves, was developed by Keiiti Aki and his coworkers in a couple of well known papers (Aki and Lee, 1976; Aki, Christofferson and Husebye 1977). Minster and Jordan (1978) applied the theory of inverse problems to the reconstruction of the tectonic plate motions, introducing the concept of ‘data importance.’ Later, tomographic studies have provided spectacular images of the Earth’s interior. Interesting papers on these inversions are by van der Hilst *et al.* (1997) and Su *et al.* (1992).

One of the major current challenges in seismic inversion is the nonlinearity of wave field inversions. This is accentuated by the fact that major experiments in the future most likely will allow us to sample the whole seismic wave field. For low frequencies, wave field inversion is linear. Dahlen (1976)

investigated the influence of lateral heterogeneity on the free oscillations. He showed that the inverse problem of estimating lateral heterogeneity of even degree from multiplet variance and skewance is linear. At the time this was published, data accuracy and unknown ellipticity splitting parameters hindered its application to real data, but later developments, including the works of Woodhouse and Dahlen (1978) on discontinuous Earth models, led to present-day successful inversions of low-frequency seismograms. In this connection the works of Woodhouse, Dziewonski, and others spring to mind.² Later, the first attempts to go to higher frequencies and nonlinear inversion were made by Nolet *et al.* (1986), and Nolet (1990).

Purely probabilistic formulations of inverse theory saw the light around 1970 (see, for instance, Kimeldorf and Wahba, 1970). In an interesting paper, Rietsch (1977) made non-trivial use of the notion of a ‘noninformative’ prior distribution for positive parameters. Jackson (1979) explicitly introduced prior information in the context of linear inverse problems, an approach that was generalized by Tarantola and Valette (1982a,b) to nonlinear problems.

There are three monographs in the area of inverse problems (from the viewpoint of data interpretation). In Tarantola (1987), the general, probabilistic formulation for nonlinear inverse problems is proposed. The small book by Menke (1984) covers several viewpoints on discrete, linear, and nonlinear inverse problems, and is easy to read. Finally, Parker (1994) exposes his view of the general theory of linear problems.

Recently, the interest in Monte Carlo methods, for the solution of inverse problems, has been increasing. Mosegaard and Tarantola (1995) proposed a generalization of the Metropolis algorithm (Metropolis *et al.*, 1953) for analysis of general inverse problems, introducing explicitly prior probability distributions, and they applied the theory to a synthetic numerical example. Monte Carlo analysis was recently applied to real data inverse problems by Mosegaard *et al.* (1997), Dahl-Jensen *et al.* (1998), Mosegaard and Rygaard-Hjalsted (1999), and Khan *et al.* (2000).

2. Elements of Probability

Probability theory is essential to our formulation of inverse theory. This chapter therefore contains a review of important elements of probability theory, with special emphasis on results that are important for the analysis of inverse problems. Of particular importance is our explicit introduction of *distance* and *volume* in data and model spaces. This has profound consequences for the notion of *conditional probability density*, which plays an important role in probabilistic inverse theory.

Also, we replace the concept of conditional probability by the more general notion of ‘conjunction’ of probabilities, this allowing us to address the more general problem where not only the data, but also the physical laws, are uncertain.

2.1 Volume

Let us consider an abstract space $\mathcal{S}$, where a point $\mathbf{x}$ is represented by some coordinates $\{x^1, x^2, \dots\}$, and let $\mathcal{A}$ be some region (subspace) of $\mathcal{S}$. The measure associating a volume $V(\mathcal{A})$ to any region $\mathcal{A}$ of $\mathcal{S}$ will be denoted the *volume measure*

$$V(\mathcal{A}) = \int_{\mathcal{A}} d\mathbf{x} v(\mathbf{x}), \quad (1)$$

where the function $v(\mathbf{x})$ is the *volume density*, and where we write $d\mathbf{x} = dx^1 dx^2 \dots$. The *volume element* is then³

$$dV(\mathbf{x}) = v(\mathbf{x}) d\mathbf{x}, \quad (2)$$

and we may write $V(\mathcal{A}) = \int_{\mathcal{A}} dV(\mathbf{x})$. A manifold is called a *metric manifold* if there is a definition of distance between points, such that the distance ds between the point of coordinates $\{x^i\}$ and the point of coordinates $\{x^i + dx^i\}$ can be expressed as⁴

$$ds^2 = g_{ij}(\mathbf{x}) dx^i dx^j, \quad (3)$$

i.e., if the notion of distance is ‘of the L_2 type.’⁵ The matrix whose entries are g_{ij} is the *metric matrix*, and an important result of differential geometry and integration theory is that the volume density of the space, $v(\mathbf{x})$, equals the square root of the determinant of the metric:

$$v(\mathbf{x}) = \sqrt{\det \mathbf{g}(\mathbf{x})}. \quad (4)$$

Example 1. In the Euclidean 3D space, using spherical coordinates, the distance element is $ds^2 = dr^2 + r^2 d\theta^2 + r^2 \sin^2 \theta d\varphi^2$, from which it follows that the metric matrix is

$$\begin{pmatrix} g_{rr} & g_{r\theta} & g_{r\varphi} \\ g_{\theta r} & g_{\theta\theta} & g_{\theta\varphi} \\ g_{\varphi r} & g_{\varphi\theta} & g_{\varphi\varphi} \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & r^2 & 0 \\ 0 & 0 & r^2 \sin^2 \theta \end{pmatrix}. \quad (5)$$

The volume density equals the metric determinant $v(r, \theta, \varphi) = \sqrt{\det \mathbf{g}(r, \theta, \varphi)} = r^2 \sin \theta$ and therefore the volume element is $dV(r, \theta, \varphi) = v(r, \theta, \varphi) dr d\theta d\varphi = r^2 \sin \theta dr d\theta d\varphi$.

2.2 Probability

Assume that we have defined over the space, not only the volume $V(\mathcal{A})$ of a region $\mathcal{A}$ of the space, but also its *probability* $P(\mathcal{A})$, which is assumed to satisfy the Kolmogorov axioms (Kolmogorov, 1933). This probability is assumed to be describable in terms of a probability density $f(x)$ through the expression

$$P(\mathcal{A}) = \int_{\mathcal{A}} d\mathbf{x} f(\mathbf{x}). \quad (6)$$

It is well known that, in a change of coordinates over the space, a probability density changes its value: it is multiplied

by the Jacobian of the transformation (this is the *Jacobian rule*). Normally, the probability of the whole space is normalized to one. If it is not normalizable, we do not say that we have a probability, but a ‘measure.’ We can state here the following postulate.

Postulate 1. *Given a space $\mathcal{X}$ over which a volume measure $V(\cdot)$ is defined. Any other measure (normalizable or not) $M(\cdot)$ considered over $\mathcal{X}$ is absolutely continuous with respect to $V(\cdot)$, i.e., the measure $M(\mathcal{A})$ of any region $\mathcal{A} \subset \mathcal{X}$ with vanishing volume must be zero: $V(\mathcal{A}) = 0 \Rightarrow M(\mathcal{A}) = 0$.*

2.3 Homogeneous Probability Distributions

In some parameter spaces, there is an obvious definition of distance between points, and therefore of volume. For instance, in the 3D Euclidean space the distance between two points is just the Euclidean distance (which is invariant under translations and rotations). Should we choose to parametrize the position of a point by its Cartesian coordinates $\{x, y, z\}$, the volume element in the space would be $dV(x, y, z) = dx dy dz$, while if we choose to use geographical coordinates, the volume element would be $dV(r, \theta, \varphi) = r^2 \sin \theta dr d\theta d\varphi$.

Definition. *The homogeneous probability distribution is the probability distribution that assigns to each region of the space a probability proportional to the volume of the region.*

Then, which probability density represents such a homogeneous probability distribution? Let us give the answer in three steps.

- If we use Cartesian coordinates $\{x, y, z\}$, as we have $dV(x, y, z) = dx dy dz$, the probability density representing the homogeneous probability distribution is constant: $f(x, y, z) = k$.
- If we use geographical coordinates $\{r, \theta, \varphi\}$, as we have $dV(r, \theta, \varphi) = r^2 \sin \theta dr d\theta d\varphi$, the probability density representing the homogeneous probability distribution is $g(r, \theta, \varphi) = kr^2 \sin \theta$.
- Finally, if we use an arbitrary system of coordinates $\{u, v, w\}$, in which the volume element of the space is $dV(u, v, w) = v(u, v, w) du dv dw$, the homogeneous probability distribution is represented by the probability density $h(u, v, w) = kv(u, v, w)$.

This is obviously true, since if we calculate the probability of a region $\mathcal{A}$ of the space, with volume $V(\mathcal{A})$, we get a number proportional to $V(\mathcal{A})$.

From these observations we can arrive at conclusions that are of general validity. First, the homogeneous probability distribution over some space is represented by a constant

probability density **only** if the space is flat (in which case rectilinear systems of coordinates exist) and if we use Cartesian (or rectilinear) coordinates. The other conclusions can be stated as rules:

Rule 1. *The probability density representing the homogeneous probability distribution is easily obtained if the expression of the volume element $dV(u_1, u_2, \dots) = v(u_1, u_2, \dots) du_1 du_2 \dots$ of the space is known, as it is then given by $h(u_1, u_2, \dots) = kv(u_1, u_2, \dots)$, where k is a proportionality constant (that may have physical dimensions).*

Rule 2. *If there is a metric $g_{ij}(u_1, u_2, \dots)$ in the space, then the volume element is given by $dV(u_1, u_2, \dots) = \sqrt{\det \mathbf{g}(u_1, u_2, \dots)} du_1 du_2 \dots$, i.e., we have $v(u_1, u_2, \dots) = \sqrt{\det \mathbf{g}(u_1, u_2, \dots)}$. The probability density representing the homogeneous probability distribution is, then, $h(u_1, u_2, \dots) = k \sqrt{\det \mathbf{g}(u_1, u_2, \dots)}$.*

Rule 3. *If the expression of the probability density representing the homogeneous probability distribution is known in one system of coordinates, then it is known in any other system of coordinates, through the Jacobian rule.*

Indeed, in the expression above, $g(r, \theta, \varphi) = kr^2 \sin \theta$, we recognize the Jacobian between the geographical and the Cartesian coordinates (where the probability density is constant).

For short, when we say *the homogeneous probability density* we mean *the probability density representing the homogeneous probability distribution*. **One should remember that, in general, the homogeneous probability density is *not* constant.**

Let us now examine ‘positive parameters,’ like a temperature, a period, or a seismic wave propagation velocity. One of the properties of the parameters we have in mind is that they occur in pairs of mutually reciprocal parameters:

Period	$T = 1/\nu$	Frequency	$\nu = 1/T$
Resistivity	$\rho = 1/\sigma$	Conductivity	$\sigma = 1/\rho$
Temperature	$T = 1/(k\beta)$	Thermodynamic parameter	$\beta = 1/(kT)$
Mass density	$\rho = 1/\ell$	Lightness	$\ell = 1/\rho$
Compressibility	$\gamma = 1/\kappa$	Bulk modulus (uncompressibility)	$\kappa = 1/\gamma$
Wave velocity	$c = 1/n$	Wave slowness	$n = 1/c$

When working with physical theories, one may freely choose one of these parameters or its reciprocal.

Sometimes these pairs of equivalent parameters come from a definition, like when we define frequency ν as a function of the period T , by $\nu = 1/T$. Sometimes these parameters arise when analyzing an idealized physical system. For instance, Hooke’s law, relating stress $\sigma_{\ell j}$ to strain $\varepsilon_{\ell j}$ can be expressed as $\sigma_{ij} = c_{ij}^{k\ell} \varepsilon_{k\ell}$, thus introducing the stiffness tensor $c_{ijk\ell}$, or as $\varepsilon_{ij} = d_{ij}^{k\ell} \sigma_{k\ell}$, thus introducing the compliance tensor

$d_{ijk\ell}$, the inverse of the stiffness tensor. Then the respective eigenvalues of these two tensors belong to the class of scalars analyzed here.

Let us take, as an example, the pair conductivity–resistivity (which may be thermal, electric, etc.). Assume we have two samples in the laboratory S_1 and S_2 whose resistivities are respectively ρ_1 and ρ_2 . Correspondingly, their conductivities are $\sigma_1 = 1/\rho_1$ and $\sigma_2 = 1/\rho_2$. How should we define the ‘distance’ between the ‘electrical properties’ of the two samples? As we have $|\rho_2 - \rho_1| \neq |\sigma_2 - \sigma_1|$, choosing one of the two expressions as the ‘distance’ would be arbitrary. Consider the following definition of ‘distance’ between the two samples:

$$D(S_1, S_2) = \left| \log \frac{\rho_2}{\rho_1} \right| = \left| \log \frac{\sigma_2}{\sigma_1} \right|. \quad (7)$$

This definition (i) treats symmetrically the two equivalent parameters ρ and σ and, more importantly, (ii) has an *invariance of scale* (what matters is how many ‘octaves’ we have between the two values, not the plain difference between the values). In fact, it is the only definition of distance between the two samples S_1 and S_2 that has an invariance of scale and is additive (i.e., $D(S_1, S_2) + D(S_2, S_3) = D(S_1, S_3)$).

Associated to the distance $D(x_1, x_2) = |\log(x_2/x_1)|$ is the distance element (differential form of the distance)

$$dL(x) = \frac{dx}{x}. \quad (8)$$

This being a ‘one-dimensional volume,’ we can now apply Rule 1 above to get the expression of the homogeneous probability density for such a positive parameter:

$$f(x) = \frac{k}{x}. \quad (9)$$

Defining the reciprocal parameter $y = 1/x$ and using the Jacobian rule, we arrive at the homogeneous probability density for y :

$$g(y) = \frac{k}{y}. \quad (10)$$

These two probability densities have the same form: the two reciprocal parameters are treated symmetrically. Introducing the logarithmic parameters

$$x^* = \log \frac{x}{x_0}; \quad y^* = \log \frac{y}{y_0}, \quad (11)$$

where x_0 and y_0 are arbitrary positive constants, and using the Jacobian rule, we arrive at the homogeneous probability densities:

$$f'(x^*) = k; \quad g'(y^*) = k. \quad (12)$$

This shows that the logarithm of a positive parameter (of the type considered above) is a ‘Cartesian’ parameter. In fact, it is the consideration of Eqs. (12), together with the Jacobian

rule, that allows full understanding of the (homogeneous) probability densities (9) and (10).

The association of the probability density $f(u) = k/u$ with positive parameters was first made by Jeffreys (1939). To honor him, we propose to use the term *Jeffreys parameters* for all the parameters of the type considered above. The $1/u$ probability density was advocated by Jaynes (1968), and a nontrivial use of it was made by Rietsch (1977) in the context of inverse problems.

Rule 4. *The homogeneous probability density for a Jeffreys quantity u is $f(u) = k/u$.*

Rule 5. *The homogeneous probability density for a ‘Cartesian parameter’ u (like the logarithm of a Jeffreys parameter, an actual Cartesian coordinate in an Euclidean space, or the Newtonian time coordinate) is $f(u) = k$. The homogeneous probability density for an angle describing the position of a point in a circle is also constant.*

If a parameter u is a Jeffreys parameter with the homogeneous probability density $f(u) = k/u$, then its inverse, its square, and, in general, any power of the parameter is also a Jeffreys parameter, as it can easily be seen using the Jacobian rule.

Rule 6. *Any power of a Jeffreys quantity (including its inverse) is a Jeffreys quantity.*

It is important to recognize when we do *not* face a Jeffreys parameter. Among the many parameters used in the literature to describe an isotropic linear elastic medium we find parameters like the Lamé’s coefficients λ and μ , the bulk modulus κ , the Poisson ratio σ , etc. A simple inspection of the theoretical range of variation of these parameters shows that the first Lamé parameter λ and the Poisson ratio σ may take negative values, so they are certainly not Jeffreys parameters. In contrast, Hooke’s law $\sigma_{ij} = c_{ijk\ell} \varepsilon_{k\ell}$, defining a linearity between stress σ_{ij} and strain ε_{ij} , defines the positive definite stiffness tensor $c_{ijk\ell}$ or, if we write $\varepsilon_{ij} = d_{ijk\ell} \sigma_{k\ell}$, defines its inverse, the compliance tensor $d_{ijk\ell}$. The two reciprocal tensors $c_{ijk\ell}$ and $d_{ijk\ell}$ are ‘Jeffreys tensors.’ This is a notion whose development is beyond the scope of this paper, but we can give the following rule.

Rule 7. *The eigenvalues of a Jeffreys tensor are Jeffreys quantities.*⁶

As the two (different) eigenvalues of the stiffness tensor $c_{ijk\ell}$ are $\lambda_\kappa = 3\kappa$ (with multiplicity 1) and $\lambda_\mu = 2\mu$ (with multiplicity 5), we see that the incompressibility modulus κ and the shear modulus μ are Jeffreys parameters⁷ (as are any parameters proportional to them, or any powers of them, including the inverses). If, for some reason, instead of working with κ and μ , we wish to work with other elastic parameters, for instance, the Young modulus Y and the

Poisson ratio σ , or the two elastic wave velocities, then the homogeneous probability distribution must be found using the Jacobian of the transformation (see Appendix H).

Some probability densities have conspicuous ‘dispersion parameters,’ like the σ ’s in the normal probability density $f(x) = k \exp\left(-\frac{(x-x_0)^2}{2\sigma^2}\right)$, in the log-normal probability $g(X) = \frac{k}{X} \exp\left(-\frac{(\log X/X_0)^2}{2\sigma^2}\right)$ or in the Fisher probability density (Fisher, 1953) $h(\vartheta, \varphi) = k \sin \theta \exp(\cos \theta / \sigma^2)$. A consistent probability model requires that when the dispersion parameter σ tends to infinity, the probability density tends to the homogeneous probability distribution. For instance, in the three examples just given, $f(x) \rightarrow k$, $g(X) \rightarrow k/X$, and $h(\theta, \varphi) \rightarrow k \sin \theta$, which are the respective homogeneous probability densities for a Cartesian quantity, a Jeffreys quantity, and the geographical coordinates on the surface of the sphere. We can state the following rule.

Rule 8. *If a probability density has some ‘dispersion parameters,’ then, in the limit where the dispersion parameters tend to infinity, the probability density must tend to the homogeneous one.*

As an example, using the normal probability density $f(x) = k \exp\left(-\frac{(x-x_0)^2}{2\sigma^2}\right)$, for a Jeffreys parameter is not consistent. Note that it would assign a finite probability to negative values of a positive parameter that, by definition, is positive. More technically, this would violate our Postulate 1. Using the log-normal probability density for a Jeffreys parameter is consistent.

There is a problem of terminology in the Bayesian literature. The homogeneous probability distribution is a very special distribution. When the problem of selecting a ‘prior’ probability distribution arises in the absence of any information, except the fundamental symmetries of the problem, one may select as prior probability distribution the homogeneous distribution. But enthusiastic Bayesians do not call it ‘homogeneous,’ but ‘noninformative.’ We cannot recommend using this terminology. The homogeneous probability distribution is as informative as any other distribution, it is just the homogeneous one (see Appendix D).

In general, each time we consider an abstract parameter space, each point being represented by some parameters $\mathbf{x} = \{x^1, x^2, \dots, x^n\}$, we will start by solving the (sometimes nontrivial) problem of defining a distance between points that respects the necessary symmetries of the problem. Only exceptionally this distance will be a quadratic expression of the parameters (coordinates) being used (i.e., only exceptionally our parameters will correspond to ‘Cartesian coordinates’ in the space). From this distance, a volume element $dV(\mathbf{x}) = v(\mathbf{x}) d\mathbf{x}$ will be deduced, from where the expression $f(\mathbf{x}) = k v(\mathbf{x})$ of the homogeneous probability density will follow. Sometimes, we can directly define the volume element, without the need of a distance. We

emphasize the need of defining a distance—or a volume element—in the parameter space, from which the notion of homogeneity will follow. With this point of view, we slightly depart from the original work by Jeffreys and Jaynes.

2.4 Conjunction of Probabilities

We shall here consider two probability distributions P and Q . We say that a probability R is a product of the two given probabilities, and is denoted $(P \wedge Q)$ if

- $P \wedge Q = Q \wedge P$;
- for any subset $\mathcal{A}$, $(P \wedge Q)(\mathcal{A}) \neq 0 \Rightarrow P(\mathcal{A}) \neq 0$ and $Q(\mathcal{A}) \neq 0$;
- if M denotes the homogeneous probability distribution, then $P \wedge M = P$.

The realization of these conditions leading to the simplest results can easily be expressed using probability densities (see Appendix G for details). If the two probabilities P and Q are represented by the two probability densities $p(\mathbf{x})$ and $q(\mathbf{x})$, respectively, and if the homogeneous probability density is represented by $\mu(\mathbf{x})$, then the probability $P \wedge Q$ is represented by a probability density, denoted $(p \wedge q)(\mathbf{x})$, that is given by

$$(p \wedge q)(\mathbf{x}) = k \frac{p(\mathbf{x}) q(\mathbf{x})}{\mu(\mathbf{x})}, \quad (13)$$

where k is a normalization constant.⁸

The two left columns of Figure 1 represent these probability densities.

FIGURE 1 The two left columns of the figure illustrate the definition of conditional probability (see text for details). The right of the figure explains that the definition of the AND operation is a generalization of the notion of conditional probability. While a conditional probability combines a probability distribution $P(\cdot)$ with an ‘event’ B , the AND operation combines two probability distributions $P(\cdot)$ and $Q(\cdot)$ defined over the same space. See text for a detailed explanation.

Example 2. On the surface of the Earth, using geographical coordinates (latitude ϑ and longitude φ), the homogeneous probability distribution is represented by the probability density $\mu(\vartheta, \varphi) = \frac{1}{4\pi} \cos \vartheta$. An estimation of the position of a floating object at the surface of the sea by an airplane navigator gives a probability distribution for the position of the object corresponding to the probability density $p(\vartheta, \varphi)$, and an independent, simultaneous estimation of the position by another airplane navigator gives a probability distribution corresponding to the probability density $q(\vartheta, \varphi)$. How do we ‘combine’ the two probability densities $p(\vartheta, \varphi)$ and $q(\vartheta, \varphi)$ to obtain a ‘resulting’ probability density? The answer is given by the conjunction of the two probability densities:

$$(p \wedge q)(\vartheta, \varphi) = k \frac{p(\vartheta, \varphi) q(\vartheta, \varphi)}{\mu(\vartheta, \varphi)}. \quad (14)$$

We emphasize here the following:

Example 2 is at the basis of the paradigm that we use below to solve inverse problems.

More generally, the conjunction of the probability densities $f_1(\mathbf{x})$, $f_2(\mathbf{x}) \dots$ is

$$\begin{aligned} h(\mathbf{x}) &= (f_1 \wedge f_2 \wedge f_3 \dots)(\mathbf{x}) \dots \\ &= k \mu(\mathbf{x}) \frac{f_1(\mathbf{x})}{\mu(\mathbf{x})} \frac{f_2(\mathbf{x})}{\mu(\mathbf{x})} \frac{f_3(\mathbf{x})}{\mu(\mathbf{x})} \dots \end{aligned} \quad (15)$$

For a formalization of the notion of conjunction of probabilities, the reader is invited to read Appendix G.

2.5 Conditional Probability Density

Given a probability distribution over a space $\mathcal{X}$, represented by the probability density $f(\mathbf{x})$, and given a subspace $\mathcal{B}$ of $\mathcal{X}$ of lower dimension, can we, in a consistent way, infer a probability distribution over $\mathcal{B}$, represented by a probability density $f(\mathbf{x}|\mathcal{B})$ (to be named the conditional probability density ‘given $\mathcal{B}$ ’)? The answer is: Using only the elements given, NO, THIS IS NOT POSSIBLE.

The usual way to induce a probability distribution on a subspace of lower dimension is to assign a ‘thickness’ to the subspace $\mathcal{B}$, to apply the general definition of conditional probability (this time to a region of $\mathcal{X}$, not to a subspace of it) and to take the limit when the ‘thickness’ tends to zero. But, as suggested in Figure 2, there are infinitely many ways to take this limit, each defining a different ‘conditional probability density’ on $\mathcal{B}$. Among the infinitely many ways to define a conditional probability density, there is one that is based on the notion of distance between points in the space, and therefore corresponds to an intrinsic definition (see Fig. 2).

Assume that the space $\mathcal{U}$ has p dimensions, the space $\mathcal{V}$ has q dimensions, and define in the $(p+q)$ -dimensional space $\mathcal{X} = (\mathcal{U}, \mathcal{V})$ a p -dimensional subspace by the p relations

$$\begin{aligned} v_1 &= v_1(u_1, u_2, \dots, u_p) \\ v_2 &= v_2(u_1, u_2, \dots, u_p) \\ &\dots = \dots \\ v_q &= v_q(u_1, u_2, \dots, u_p). \end{aligned} \quad (16)$$

FIGURE 2 An original 2D probability density, and two possible ways (among many) of defining a region of the space whose limit is a given curve. At the top is the ‘vertical’ limit, while at the bottom is the normal (or orthogonal) limit. Each possible limit defines a different ‘induced’ or ‘conditional’ probability density. Only the orthogonal limit gives an intrinsic definition (i.e., a definition invariant under any change of variables). It is, therefore, the only one examined in this work.

The restriction of a probability distribution represented by the probability density $f(\mathbf{x}) = f(\mathbf{u}, \mathbf{v})$ into the subspace defined by the constraint $\mathbf{v} = \mathbf{v}(\mathbf{u})$, can be defined with all generality when it is assumed that we have a metric defined over the $(p+q)$ -dimensional space $\mathcal{X} = (\mathcal{U}, \mathcal{V})$. Let us limit here to the special circumstance (useful for a vast majority of inverse problems⁹) where the $(p+q)$ -dimensional space $\mathcal{X}$ is built as the Cartesian product of $\mathcal{U}$ and $\mathcal{V}$ (then we write, as usual, $\mathcal{X} = \mathcal{U} \times \mathcal{V}$). In this case, there is a metric $\mathbf{g}_u$ over $\mathcal{U}$, with associated volume element $dV_u(\mathbf{u}) = \sqrt{\det \mathbf{g}_u} d\mathbf{u}$, there is a metric $\mathbf{g}_v$ over $\mathcal{V}$, with associated volume element $dV_v(\mathbf{v}) = \sqrt{\det \mathbf{g}_v} d\mathbf{v}$, and the global volume element is simply $dV(\mathbf{u}, \mathbf{v}) = dV_u(\mathbf{u}) dV_v(\mathbf{v})$.

The restriction of the probability distribution represented by the probability density $f(\mathbf{u}, \mathbf{v})$ on the subspace $\mathbf{v} = \mathbf{v}(\mathbf{u})$ (i.e., the conditional probability density given $\mathbf{v} = \mathbf{v}(\mathbf{u})$) is a probability distribution *on* the submanifold $\mathbf{v} = \mathbf{v}(\mathbf{u})$. We could choose ad-hoc coordinates over this manifold, but as there is a one-to-one correspondence between the coordinates $\mathbf{u}$ and the points on the manifold, the conditional probability density can be expressed using the coordinates $\mathbf{u}$. The restriction of $f(\mathbf{u}, \mathbf{v})$ over the submanifold $\mathbf{v} = \mathbf{v}(\mathbf{u})$ defines the probability density (see Appendix B for the more general case)

$$f_{u|v(u)}(\mathbf{u} | \mathbf{v} = \mathbf{v}(\mathbf{u})) = k f(\mathbf{u}, \mathbf{v}(\mathbf{u})) \frac{\sqrt{\det(\mathbf{g}_u + \mathbf{V}^T \mathbf{g}_v \mathbf{V})}}{\sqrt{\det \mathbf{g}_u} \sqrt{\det \mathbf{g}_v}} \Big|_{\mathbf{v} = \mathbf{v}(\mathbf{u})}, \quad (17)$$

where k is a normalizing constant, and where $\mathbf{V} = \mathbf{V}(\mathbf{u})$ is the matrix of partial derivatives (see Appendix M for a simple explicit calculation of such partial derivatives)

$$\begin{pmatrix} V_{11} & V_{12} & \cdots & V_{1p} \\ V_{21} & V_{22} & \cdots & V_{2p} \\ \vdots & \vdots & \ddots & \vdots \\ V_{q1} & V_{q2} & \cdots & V_{qp} \end{pmatrix} = \begin{pmatrix} \frac{\partial v_1}{\partial u_1} & \frac{\partial v_1}{\partial u_2} & \cdots & \frac{\partial v_1}{\partial u_p} \\ \frac{\partial v_2}{\partial u_1} & \frac{\partial v_2}{\partial u_2} & \cdots & \frac{\partial v_2}{\partial u_p} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{\partial v_q}{\partial u_1} & \frac{\partial v_q}{\partial u_2} & \cdots & \frac{\partial v_q}{\partial u_p} \end{pmatrix}. \quad (18)$$

Example 3. If the hypersurface $\mathbf{v} = \mathbf{v}(\mathbf{u})$ is defined by a constant value of $\mathbf{v}$, say $\mathbf{v} = \mathbf{v}_0$, then Eq. (17) reduces to

$$f_{u|v}(\mathbf{u} | \mathbf{v} = \mathbf{v}_0) = k f(\mathbf{u}, \mathbf{v}_0) = \frac{f(\mathbf{u}, \mathbf{v}_0)}{\int_{\mathcal{U}} d\mathbf{u} f(\mathbf{u}, \mathbf{v}_0)}. \quad (19)$$

Elementary definitions of conditional probability density are not based on this notion of distance-based uniform convergence, but use other, ill-defined limits. This is a mistake that, unfortunately, pollutes many scientific works. See Appendix P, in particular, for a discussion on the ‘Borel paradox.’

Equation (17) defines the conditional $f_{u|v(u)}(\mathbf{u} | \mathbf{v} = \mathbf{v}(\mathbf{u}))$. Should the relation $\mathbf{v} = \mathbf{v}(\mathbf{u})$ be invertible, it would correspond to a change of variables. It is then possible to show that the alternative conditional $f_{v|u(v)}(\mathbf{v} | \mathbf{u} = \mathbf{u}(\mathbf{v}))$ is related to $f_{u|v(u)}(\mathbf{u} | \mathbf{v} = \mathbf{v}(\mathbf{u}))$ through the Jacobian rule. This is a property that elementary definitions of conditional probability do not share.

2.6 Marginal Probability Density

In the special circumstance described above, where we have a Cartesian product of two spaces, $\mathcal{X} = \mathcal{U} \times \mathcal{V}$, given a ‘joint’ probability density $f(\mathbf{u}, \mathbf{v})$, it is possible to give an intrinsic sense to the definitions

$$f_u(\mathbf{u}) = \int_{\mathcal{V}} d\mathbf{v} f(\mathbf{u}, \mathbf{v}); \quad f_v(\mathbf{v}) = \int_{\mathcal{U}} d\mathbf{u} f(\mathbf{u}, \mathbf{v}). \quad (20)$$

These two densities are called *marginal probability densities*. Their intuitive interpretation is clear, as the ‘projection’ of the joint probability density respectively over $\mathcal{U}$ and over $\mathcal{V}$.

2.7 Independence and Bayes Theorem

Dropping the index 0 in Eq. (19) and using the second of Eqs. (20) gives

$$f_{u|v}(\mathbf{u} | \mathbf{v}) = \frac{f(\mathbf{u}, \mathbf{v})}{f_v(\mathbf{v})}, \quad (21)$$

or, equivalently, $f(\mathbf{u}, \mathbf{v}) = f_{u|v}(\mathbf{u} | \mathbf{v}) f_v(\mathbf{v})$. As we can also define $f_{v|u}(\mathbf{v} | \mathbf{u})$, we have the two equations

$$\begin{aligned} f(\mathbf{u}, \mathbf{v}) &= f_{u|v}(\mathbf{u} | \mathbf{v}) f_v(\mathbf{v}) \\ f(\mathbf{u}, \mathbf{v}) &= f_{v|u}(\mathbf{v} | \mathbf{u}) f_u(\mathbf{u}), \end{aligned} \quad (22)$$

that can be read as follows: ‘When we work in a space that is the Cartesian product $\mathcal{U} \times \mathcal{V}$ of two subspaces, a joint probability density can always be expressed as the product of a conditional times a marginal.’

From these last equations there follows the expression

$$f_{u|v}(\mathbf{u} | \mathbf{v}) = \frac{f_{v|u}(\mathbf{v} | \mathbf{u}) f_u(\mathbf{u})}{f_v(\mathbf{v})}, \quad (23)$$

known as the *Bayes theorem*, and generally used as the starting point for solving inverse problems. We do not think this is a useful setting, and we prefer here *not* to use the Bayes theorem (or, more precisely, not to use the intuitive paradigm usually associated with it).

It also follows from Eqs. (22) that the two conditions

$$f_{u|v}(\mathbf{u} | \mathbf{v}) = f_u(\mathbf{u}); \quad f_{v|u}(\mathbf{v} | \mathbf{u}) = f_v(\mathbf{v}) \quad (24)$$

are equivalent. It is then said that $\mathbf{u}$ and $\mathbf{v}$ are *independent parameters* (with respect to the probability density $f(\mathbf{u}, \mathbf{v})$). The term ‘independent’ is easy to understand, as the conditional of any of the two (vector) variables, given the other variable equals the (unconditional) marginal of the variable. Then, one clearly has

$$f(\mathbf{u}, \mathbf{v}) = f_u(\mathbf{u}) f_v(\mathbf{v}) \quad (25)$$

i.e., for independent variables, the joint probability density can be simply expressed as the product of the two marginals.

3. Monte Carlo Methods

When a probability distribution has been defined, we face the problem of how to ‘use’ it. The definition of ‘central estimators’ (such as the mean or the median) and ‘estimators of dispersion’ (such as the covariance matrix) lacks generality as it is quite easy to find examples (such as multimodal distributions in highly-dimensional spaces) where these estimators fail to have any interesting meaning.

When a probability distribution has been defined over a space of low dimension (say, from one to four dimensions) we can directly represent the associated probability density. This is trivial in one or two dimensions. It is easy in three dimensions, and some tricks may allow us to represent a four-dimensional probability distribution, but clearly this approach cannot be generalized to the high dimensional case.

Let us explain the only approach that seems practical, with help of Figure 3. At the left of the figure, there is an explicit representation of a 2D probability distribution (by means of the associated probability density or the associated (2D) volumetric probability). In the middle, some random points have been generated (using the Monte Carlo method about to be described). It is clear that, if we make a histogram with these points, in the limit of a sufficiently large number of points we recover the representation at the left. Disregarding the histogram possibility, we can concentrate on the individual points. In the 2D example of the figure we have actual points in a plane. If the problem is multidimensional, each ‘point’ may correspond to some abstract notion. For instance, for a geophysicist a ‘point’ may be a given model of the Earth. This model may be represented in some way, for instance, by a color plot. Then a collection of ‘points’ is a collection of such pictures. Our experience shows that, given a collection of randomly generated ‘models,’ the human eye–brain system is extremely good at apprehending the basic characteristics of the underlying probability distribution, including possible multimodalities, correlations, etc.

When such a (hopefully large) collection of random models is available, we can also answer quite interesting questions. For instance, a geologist might ask: *at which depth*

FIGURE 3 An explicit representation of a 2D probability distribution and the sampling of it, using Monte Carlo methods. While the representation at the top left cannot be generalized to high dimensions, the examination of a collection of points can be done in arbitrary dimensions. Practically, Monte Carlo generation of points is done through a ‘random walk’ where a ‘new point’ is generated in the vicinity of the previous point.

is that subsurface structure? To answer this, we can make a histogram of the depth of the given geological structure over the collection of random models, and the histogram is the answer to the question. *What is the probability of having a low-velocity zone around a given depth?* The ratio of the number of models presenting such a low-velocity zone over the total number of models in the collection gives the answer (if the collection of models is large enough).

This is essentially what we propose: looking at a large number of randomly generated models in order to intuitively apprehend the basic properties of the probability distribution, followed by calculation of the probabilities of all interesting ‘events.’

Practically, as we will see, the random sampling is not made by generating points independently of each other. Rather, as suggested in the last image of Figure 3, it is done through a ‘random walk’ where a ‘new point’ is generated in the vicinity of the previous point.

Monte Carlo methods have a random generator at their core. At present, Monte Carlo methods are typically implemented on digital computers, and are based on pseudo random generation of numbers.¹⁰ As we shall see, any conceivable operation on probability densities (e.g., computing marginals and conditionals, integration, conjunction (the AND operation), etc.) has its counterpart in an operation on/by their corresponding Monte Carlo algorithms.

Inverse problems are often formulated in high-dimensional spaces. In this case a certain class of Monte Carlo algorithms,

the so-called *importance sampling algorithms*, come to the rescue, allowing us to sample the space with a sampling density proportional to the given probability density. In this case excessive (and useless) sampling of low-probability areas of the space is avoided. This is not only important, but in fact vital in high-dimensional spaces.

Another advantage of the importance sampling Monte Carlo algorithms is that we need not have a closed-form mathematical expression for the probability density that we want to sample. Only an algorithm that allows us to evaluate it at a given point in the space is needed. This has considerable practical advantage in analysis of inverse problems where computer-intensive evaluation of, for example, misfit functions plays an important role in calculation of certain probability densities.

Given a probability density that we wish to sample, and a class of Monte Carlo algorithms that samples this density, which one of the algorithms should we choose? Practically, the problem here is to find the most efficient of these algorithms. This is an interesting and difficult problem for which we will not go into detail here. We will, later in this chapter, limit ourselves to only two general methods that are recommendable in many practical situations.

3.1 Random Walks

To escape the dimensionality problem, *any* sampling of a probability density for which point values are available only upon request has to be based on a *random walk*, i.e., in a generation of successive points with the constraint that point $\mathbf{x}_{i+1}$ sampled in iteration $(i+1)$ is in the vicinity of the point $\mathbf{x}_i$ sampled in iteration i . The simplest of the random walks are generated by the so-called Markov Chain Monte Carlo (MCMC) algorithms, where the point $\mathbf{x}_{i+1}$ depends on the point $\mathbf{x}_i$, but not on previous points. We will concentrate on these algorithms here.

If random rules have been defined to select points such that the probability of selecting a point in the infinitesimal ‘box’ $dx_1 \cdots dx_N$ is $p(\mathbf{x}) dx_1 \cdots dx_N$, then the points selected in this way are called *samples* of the probability density $p(\mathbf{x})$. Depending on the rules defined, successive samples $i, j, k, \dots$ may be dependent or independent.

3.2 The Metropolis Rule

The most common Monte Carlo sampling methods are the Metropolis sampler (described below) and the Gibbs sampler (Geman and Geman, 1984). As we believe that the Gibbs sampler is only superior to the Metropolis sampler in low-dimensional problems, we restrict ourselves here to the presentation of the latter.

Consider the following situation. Some random rules define a random walk that samples the probability density $f(\mathbf{x})$. At a given step, the random walker is at point $\mathbf{x}_j$, and

the application of the rules would lead to a transition to point $\mathbf{x}_i$. By construction, when all such ‘proposed transitions’ $\mathbf{x}_i \leftarrow \mathbf{x}_j$ are always accepted, the random walker will sample the probability density $f(\mathbf{x})$. Instead of always accepting the proposed transition $\mathbf{x}_i \leftarrow \mathbf{x}_j$, we reject it sometimes by using the following rule to decide if it is allowed to move to $\mathbf{x}_i$ or if it must stay at $\mathbf{x}_j$:

- If $g(\mathbf{x}_i)/\mu(\mathbf{x}_i) \geq g(\mathbf{x}_j)/\mu(\mathbf{x}_j)$, then accept the proposed transition to $\mathbf{x}_i$.
- If $g(\mathbf{x}_i)/\mu(\mathbf{x}_i) < g(\mathbf{x}_j)/\mu(\mathbf{x}_j)$, then decide randomly to move to $\mathbf{x}_i$, or to stay at $\mathbf{x}_j$, with the following probability of accepting the move to $\mathbf{x}_i$:

$$P = \frac{g(\mathbf{x}_i)/\mu(\mathbf{x}_i)}{g(\mathbf{x}_j)/\mu(\mathbf{x}_j)}. \quad (26)$$

Then we have the following theorem.

Theorem 1. *The random walker samples the conjunction $h(\mathbf{x})$ of the probability densities $f(\mathbf{x})$ and $g(\mathbf{x})$*

$$h(\mathbf{x}) = k f(\mathbf{x}) \frac{g(\mathbf{x})}{\mu(\mathbf{x})} = k \frac{f(\mathbf{x}) g(\mathbf{x})}{\mu(\mathbf{x})} \quad (27)$$

(see Appendix O for a demonstration).

It should be noted here that this algorithm nowhere requires the probability densities to be normalized. This is of vital importance in practice, since it allows sampling of probability densities whose values are known only in points already sampled by the algorithm. Obviously, such probability densities cannot be normalized. Also, the fact that our theory also allows unnormalizable probability densities will not cause any trouble in the application of the above algorithm.

The algorithm above is reminiscent (see Appendix O) of the Metropolis algorithm (Metropolis *et al.*, 1953), originally designed to sample the Gibbs–Boltzmann distribution.¹¹ Accordingly, we will refer to the above acceptance rule as the *Metropolis rule*.

3.3 The Cascaded Metropolis Rule

As above, assume that some random rules define a random walk that samples the probability density $f_1(\mathbf{x})$. At a given step, the random walker is at point $\mathbf{x}_j$.

- (1) Apply the rules that unthwarted would generate samples distributed according to $f_1(\mathbf{x})$, to propose a new point $\mathbf{x}_i$.
- (2) If $f_2(\mathbf{x}_i)/\mu(\mathbf{x}_i) \geq f_2(\mathbf{x}_j)/\mu(\mathbf{x}_j)$, go to point 3; if $f_2(\mathbf{x}_i)/\mu(\mathbf{x}_i) < f_2(\mathbf{x}_j)/\mu(\mathbf{x}_j)$, then decide randomly to go to point 3 or to go back to point 1, with the following probability of going to point 3: $P = (f_2(\mathbf{x}_i)/\mu(\mathbf{x}_i)) / (f_2(\mathbf{x}_j)/\mu(\mathbf{x}_j))$.

- (3) If $f_3(\mathbf{x}_i)/\mu(\mathbf{x}_i) \geq f_3(\mathbf{x}_j)/\mu(\mathbf{x}_j)$, go to point 4; if $f_3(\mathbf{x}_i)/\mu(\mathbf{x}_i) < f_3(\mathbf{x}_j)/\mu(\mathbf{x}_j)$, then decide randomly to go to point 4 or to go back to point 1, with the following probability of going to point 4: $P = (f_3(\mathbf{x}_i)/\mu(\mathbf{x}_i)) / (f_3(\mathbf{x}_j)/\mu(\mathbf{x}_j))$.

...

- (n) If $f_n(\mathbf{x}_i)/\mu(\mathbf{x}_i) \geq f_n(\mathbf{x}_j)/\mu(\mathbf{x}_j)$, then accept the proposed transition to $\mathbf{x}_i$; if $f_n(\mathbf{x}_i)/\mu(\mathbf{x}_i) < f_n(\mathbf{x}_j)/\mu(\mathbf{x}_j)$, then decide randomly to move to $\mathbf{x}_i$, or to stay at $\mathbf{x}_j$, with the following probability of accepting the move to $\mathbf{x}_i$: $P = (f_n(\mathbf{x}_i)/\mu(\mathbf{x}_i)) / (f_n(\mathbf{x}_j)/\mu(\mathbf{x}_j))$.

Then we have the following theorem.

Theorem 2. *The random walker samples the conjunction $h(\mathbf{x})$ of the probability densities $f_1(\mathbf{x}), f_2(\mathbf{x}), \dots, f_n(\mathbf{x})$:*

$$h(\mathbf{x}) = k f_1(\mathbf{x}) \frac{f_2(\mathbf{x})}{\mu(\mathbf{x})} \dots \frac{f_n(\mathbf{x})}{\mu(\mathbf{x})}. \quad (28)$$

(see the supplementary materials to this chapter on the attached Handbook CD for a demonstration).

3.4 Initiating a Random Walk

Consider the problem of obtaining samples of a probability density $h(\mathbf{x})$ defined as the conjunction of some probability densities $f_1(\mathbf{x}), f_2(\mathbf{x}), f_3(\mathbf{x}), \dots$,

$$h(\mathbf{x}) = k f_1(\mathbf{x}) \frac{f_2(\mathbf{x})}{\mu(\mathbf{x})} \frac{f_3(\mathbf{x})}{\mu(\mathbf{x})} \dots, \quad (29)$$

and let us examine three common situations.

We start with a random walk that samples $f_1(\mathbf{x})$ (optimal situation): This corresponds to the basic algorithm where we know how to produce a random walk that samples $f_1(\mathbf{x})$, and we only need to modify it, taking into account the values $f_2(\mathbf{x})/\mu(\mathbf{x}), f_3(\mathbf{x})/\mu(\mathbf{x}), \dots$, using the cascaded Metropolis rule, to obtain a random walk that samples $h(\mathbf{x})$.

We start with a random walk that samples the homogeneous probability density $\mu(\mathbf{x})$: We can write Eq. (29) as

$$h(\mathbf{x}) = k \left(\left(\mu(\mathbf{x}) \frac{f_1(\mathbf{x})}{\mu(\mathbf{x})} \right) \frac{f_2(\mathbf{x})}{\mu(\mathbf{x})} \right) \dots. \quad (30)$$

The expression corresponds to the case where we are not able to start with a random walk that samples $f_1(\mathbf{x})$, but we have a random walk that samples the homogeneous probability density $\mu(\mathbf{x})$. Then, with respect to the example just mentioned, there is one extra step to be added, taking into account the values of $f_1(\mathbf{x})/\mu(\mathbf{x})$.

We start with an arbitrary random walk (worst situation): In the situation where we are not able to directly define a random walk that samples the homogeneous probability distribution, but only one that samples some arbitrary (but known) probability distribution $\psi(\mathbf{x})$, we can write Eq. (29) in the form

$$h(\mathbf{x}) = k \left(\left(\left(\psi(\mathbf{x}) \frac{\mu(\mathbf{x})}{\psi(\mathbf{x})} \right) \frac{f_1(\mathbf{x})}{\mu(\mathbf{x})} \right) \frac{f_2(\mathbf{x})}{\mu(\mathbf{x})} \right) \dots. \quad (31)$$

Then, with respect to the example just mentioned, there is one more extra step to be added, taking into account the values of $\mu(\mathbf{x})/\psi(\mathbf{x})$. Note that the closer $\psi(\mathbf{x})$ is to $\mu(\mathbf{x})$, the more efficient will be the first modification of the random walk.

3.5 Convergence Issues

When has a random walk visited enough points in the space so that a probability density has been sufficiently sampled? This is a complex issue, and it is easy to overlook its importance. There is no general rule: Each problem has its own ‘physics,’ and the experience of the ‘implementer’ is crucial here.

Many methods that work for low dimension completely fail when the number of dimensions is high. Typically, a random walk select a random direction and, then, a random step along that direction. The notion of ‘direction’ in a high-dimensional space is far from the intuitive one we get in the familiar three-dimensional space. Any serious discussion on this issue must be problem-dependent, so we do not even attempt one here.

Obviously, a necessary condition for adequate sampling is that any ‘output’ from the algorithm must ‘look stationary.’

4. Probabilistic Formulation of Inverse Problems

A so-called ‘inverse problem’ arises when a usually complex measurement is made, and information on unknown parameters of the physical system is sought. Any measurement is indirect (we may weigh a mass by observing the displacement of the cursor of a balance), and therefore a possibly nontrivial analysis of uncertainties must be done. Any guide describing good experimental practice (see, for instance the ISO’s *Guide to the Expression of Uncertainty in Measurement* (ISO, 1993) or the shorter description by Taylor and Kuyatt, 1994) acknowledges that a measurement involves, at least, two different sources of uncertainties: those estimated using statistical methods, and those estimated using subjective, common-sense estimations. Both are described using the axioms of probability theory, and this chapter clearly takes the probabilistic point of view for developing inverse theory.

4.1 Model Parameters and Observable Parameters

Although the separation of all the variables of a problem into two groups, ‘directly observable parameters’ (or ‘data’) and ‘model parameters’, may sometimes be artificial, we take this point of view here, since it allows us to propose a simple setting for a wide class of problems.

We may have in mind a given physical system, like the whole Earth or a small crystal under our microscope. The system (or a given state of the system) may be described by assigning values to a given set of parameters $\mathbf{m} = \{m^1, m^2, \dots, m^{NM}\}$, which we will name the *model parameters*.

Let us assume that we make observations on this system. Although we are interested in the parameters $\mathbf{m}$, they may not be directly observable, so we make indirect measurements such as obtaining seismograms at the Earth’s surface for analyzing the Earth’s interior, or making spectroscopic measurements for analyzing the chemical properties of a crystal. The set of (*directly*) *observable parameters* (or, by abuse of language, the set of *data parameters*) will be represented by $\mathbf{d} = \{d^1, d^2, \dots, d^{ND}\}$.

We assume that we have a physical theory that can be used to solve the *forward problem*, i.e., that given an arbitrary model $\mathbf{m}$, it allows us to predict the theoretical data values $\mathbf{d}$ that an ideal measurement should produce (if $\mathbf{m}$ were the actual system). The generally nonlinear function that associates with any model $\mathbf{m}$ the theoretical data values $\mathbf{d}$ may be represented by a notation such as

$$d^i = f^i(m^1, m^2, \dots, m^{NM}); \quad i = 1, 2, \dots, ND, \quad (32)$$

or, for short,

$$\mathbf{d} = \mathbf{f}(\mathbf{m}). \quad (33)$$

It is in fact this expression that separates the whole set of our parameters into the subsets $\mathbf{d}$ and $\mathbf{m}$, although sometimes there is no difference in nature between the parameters in $\mathbf{d}$ and the parameters in $\mathbf{m}$. For instance, in the classical inverse problem of estimating the hypocenter coordinates of an earthquake, we may put in $\mathbf{d}$ the arrival times of the seismic waves at seismic observatories, and we need to put in $\mathbf{m}$, besides the hypocentral coordinates, the coordinates defining the location of the seismometers—as these are parameters that are needed to compute the travel times—although we estimate arrival times of waves and coordinates of the seismic observatories using similar types of measurements.

4.2 Prior Information on Model Parameters

In a typical geophysical problem, the model parameters contain geometrical parameters (positions and sizes of geological bodies) and physical parameters (values of the mass

density, of the elastic parameters, the temperature, the porosity, etc.).

The *prior information* on these parameters is all the information we possess independently of the particular measurements that will be considered as ‘data’ (to be described below). This prior probability distribution is generally quite complex, as the model space may be high-dimensional, and the parameters may have nonstandard probability densities.

To this generally complex probability distribution over the model space corresponds a probability density that we denote $\rho_m(\mathbf{m})$.

If an explicit expression for the probability density $\rho_m(\mathbf{m})$ is known, it can be used in analytical developments. But such an explicit expression is, by no means, necessary. Using Monte Carlo methods, all that is needed is a set of probabilistic rules that allows us to generate samples distributed according to $\rho_m(\mathbf{m})$ in the model space (Mosegaard and Tarantola, 1995).

Example 4. Appendix E presents an example of prior information for the case of an Earth model consisting of a stack of horizontal layers with variable thickness and uniform mass density.

4.3 Measurements and Experimental Uncertainties

Observation of geophysical phenomena is represented by a set of parameters $\mathbf{d}$ that we usually call data. These parameters result from prior measurement operations, and they are typically seismic vibrations on the instrument site, arrival times of seismic phases, gravity or electromagnetic fields. As in any measurement, the data are determined with an associated uncertainty, described by a probability density over the data parameter space, that we denote here $\rho_d(\mathbf{d})$. This density describes not only marginals on individual datum values, but also possible cross-relations in data uncertainties.

Although the instrumental errors are an important source of data uncertainties, in geophysical measurements there are other sources of uncertainty. The errors associated with the positioning of the instruments, the environmental noise, and the human factor (like for picking arrival times) are also relevant sources of uncertainty.

Example 5. Nonanalytic Probability Density. Assume that we wish to measure the time t of occurrence of some physical event. It is often assumed that the result of a measurement corresponds to something like

$$t = t_0 \pm \sigma. \quad (34)$$

An obvious question is the exact meaning of the $\pm\sigma$. Has the experimenter in mind that she or he is absolutely certain that the actual arrival time satisfies the strict conditions

FIGURE 4 What has an experimenter in mind when she or he describes the result of a measurement by something like $t = t_0 \pm \sigma$?

$t_0 - \sigma \leq t \leq t_0 + \sigma$, or has she or he in mind something like a Gaussian probability, or some other probability distribution (see Fig. 4)? We accept, following ISO's recommendations (1993) that the result of any measurement has a probabilistic interpretation, with some sources of uncertainty being analyzed using statistical methods ('type A' uncertainties), and other sources of uncertainty being evaluated by other means (for instance, using Bayesian arguments) ('type B' uncertainties). But, contrary to ISO suggestions, we do not assume that the Gaussian model of uncertainties should play any central role. In an extreme example, we may well have measurements whose probabilistic description may correspond to a multimodal probability density. Figure 5 shows a typical example for a seismologist: the measurement on a seismogram of the arrival time of a certain seismic wave, in the case one hesitates in the phase identification or in the identification of noise and signal. In this case the probability density for the arrival of the seismic phase does not have an explicit expression like $f(t) = k \exp(-(t - t_0)^2 / (2\sigma^2))$, but is a numerically defined function.

Example 6. The Gaussian model for uncertainties. The simplest probabilistic model that can be used to describe experimental uncertainties is the Gaussian model

$$\rho_d(\mathbf{d}) = k \exp\left(-\frac{1}{2}(\mathbf{d} - \mathbf{d}_{\text{obs}})^T \mathbf{C}_D^{-1} (\mathbf{d} - \mathbf{d}_{\text{obs}})\right). \quad (35)$$

It is here assumed that we have some 'observed data values' $\mathbf{d}_{\text{obs}}$ with uncertainties described by the covariance matrix $\mathbf{C}_D$. If the uncertainties are uncorrelated,

$$\rho_d(\mathbf{d}) = k \exp\left(-\frac{1}{2} \sum_i \left(\frac{d^i - d_{\text{obs}}^i}{\sigma^i}\right)^2\right), \quad (36)$$

where the σ^i are the 'standard deviations.'

Example 7. The generalized Gaussian model for uncertainties. An alternative to the Gaussian model is to use the

FIGURE 5 A seismologist tries to measure the arrival time of a seismic wave at a seismic station, by 'reading' the seismogram at the top of the figure. The seismologist may find quite likely that the arrival time of the wave is between times t_3 and t_4 , and believe that what is before t_3 is just noise. But if there is a significant probability that the signal between t_1 and t_2 is not noise but the actual arrival of the wave, then the seismologist should define a bimodal probability density, as the one suggested at the bottom of the figure. Typically, the actual form of each peak of the probability density is not crucial (here, box-car functions are chosen), but the position of the peaks is important. Rather than assigning a zero probability density to the zones outside the two intervals, it is safer (more 'robust') to attribute some small 'background' value, as we may never exclude some unexpected source of error.

Laplacian (double exponential) model for uncertainties,

$$\rho_d(\mathbf{d}) = k \exp \left(- \sum_i \frac{|d^i - d_{\text{obs}}^i|}{\sigma^i} \right). \quad (37)$$

While the Gaussian model leads to least-squares-related methods, this Laplacian model leads to absolute-values methods (see Section 4.5.2), well known for producing robust¹² results. More generally, there is the L_p model of uncertainties

$$\rho_p(\mathbf{d}) = k \exp \left(- \frac{1}{p} \sum_i \frac{|d^i - d_{\text{obs}}^i|^p}{(\sigma^i)^p} \right) \quad (38)$$

(see Fig. 6).

4.4 Joint “Prior” Probability Distribution in the $(\mathcal{M}, \mathcal{D})$ Space

We have just seen that the prior information on model parameters can be described by a probability density in the model space, $\rho_m(\mathbf{m})$, and that the result of measurements can be described by a probability density in the data space $\rho_d(\mathbf{d})$. As by ‘prior’ information on model parameters we mean information obtained *independently* from the measurements (it often represents information we had before the measurements were made), we can use the notion of independency of variables of Section 2.6 to define a joint probability density in the $\mathcal{X} = (\mathcal{M}, \mathcal{D})$ space as the product of the two ‘marginals’

$$\rho(\mathbf{x}) = \rho(\mathbf{m}, \mathbf{d}) = \rho_m(\mathbf{m}) \rho_d(\mathbf{d}). \quad (39)$$

Although we have introduced $\rho_m(\mathbf{m})$ and $\rho_d(\mathbf{d})$ separately, and we have suggested building a probability distribution in the $(\mathcal{M}, \mathcal{D})$ space by the multiplication (39), we may have a more general situation where the information we have on $\mathbf{m}$ and on $\mathbf{d}$ is not independent. So, in what follows, let us assume that we have some information in the $\mathcal{X} = (\mathcal{M}, \mathcal{D})$ space, represented by the ‘joint’ probability density

$$\rho(\mathbf{x}) = \rho(\mathbf{m}, \mathbf{d}), \quad (40)$$

and let us consider Eq. (39) as just a special case.

Let us in the rest of this chapter denote by $\mu(\mathbf{x})$ the probability density representing the homogeneous probability distribution, as introduced in Section 2.2. We may remember here the Rule 8, stating that the limit of a consistent probability density must be the homogeneous one, so we may formally write

$$\mu(\mathbf{x}) = \lim_{\text{infinite dispersions}} \rho(\mathbf{x}). \quad (41)$$

When the partition (39) holds, then, typically (see Rule 8),

$$\mu(\mathbf{x}) = \mu(\mathbf{m}, \mathbf{d}) = \mu_m(\mathbf{m}) \mu_d(\mathbf{d}). \quad (42)$$

4.5 Physical Laws as Mathematical Functions

4.5.1 Physical Laws

Physics analyzes the correlations existing between physical parameters. In standard mathematical physics, these correlations are represented by ‘equalities’ between physical parameters (as when we write $\mathbf{F} = m \mathbf{a}$ to relate the force

FIGURE 6 Generalized Gaussian for values of the parameter $p = 1, \sqrt{2}, 2, 4, 8$, and ∞ .

$\mathbf{F}$ applied to a particle, the mass m of the particle and the acceleration $\mathbf{a}$). In the context of inverse problems, this corresponds to assuming that we have a function from the ‘parameter space’ to the ‘data space’ that we may represent as

$$\mathbf{d} = \mathbf{f}(\mathbf{m}) . \quad (43)$$

We do not mean that the relation is necessarily explicit. Given $\mathbf{m}$ we may need to solve a complex system of equations in order to get $\mathbf{d}$, but this nevertheless defines a function $\mathbf{m} \rightarrow \mathbf{d} = \mathbf{f}(\mathbf{m})$.

At this point, given the probability density $\rho(\mathbf{m}, \mathbf{d})$ and given the relation $\mathbf{d} = \mathbf{f}(\mathbf{m})$, we can define the associated conditional probability density $\rho_{m|d(m)}(\mathbf{m} | \mathbf{d} = \mathbf{f}(\mathbf{m}))$. We could here use the more general definition of conditional probability density of Appendix B, but let us simplify the text by using a simplifying assumption: that the total parameter space $(\mathcal{M}, \mathcal{D})$ is just the Cartesian product $\mathcal{M} \times \mathcal{D}$ of the model parameter space $\mathcal{M}$ times the space of directly observable parameters (or ‘data space’) $\mathcal{D}$. Then, rather than a general metric in the total space, we have a metric $\mathbf{g}_m$ over the model parameter space $\mathcal{M}$ and a metric $\mathbf{g}_d$ over the data space, and the total metric is just the Cartesian product of the two metrics. In particular, then, the total volume element in the space, $dV(\mathbf{m}, \mathbf{d})$ is just the product of the two volume elements in the model parameter space and the data space: $dV(\mathbf{m}, \mathbf{d}) = dV_m(\mathbf{m}) dV_d(\mathbf{d})$. Most inverse problems satisfy this assumption.¹³ In this setting, the formulas of Section 2.4 are valid.

4.5.2 Inverse Problems

In the $(\mathcal{M}, \mathcal{D}) = \mathcal{M} \times \mathcal{D}$ space, we have the probability density $\rho(\mathbf{m}, \mathbf{d})$ and we have the hypersurface defined by the relation $\mathbf{d} = \mathbf{f}(\mathbf{m})$. The natural way to ‘compose’ these two kinds of information is by defining the conditional probability density induced by $\rho(\mathbf{m}, \mathbf{d})$ on the hypersurface $\mathbf{d} = \mathbf{f}(\mathbf{m})$,

$$\sigma_m(\mathbf{m}) \equiv \rho_{m|d(m)}(\mathbf{m} | \mathbf{d} = \mathbf{f}(\mathbf{m})) , \quad (44)$$

this gives (see Eq. (17))

$$\sigma_m(\mathbf{m}) = k \rho(\mathbf{m}, \mathbf{f}(\mathbf{m})) \frac{\sqrt{\det(\mathbf{g}_m + \mathbf{F}^T \mathbf{g}_d \mathbf{F})}}{\sqrt{\det \mathbf{g}_m} \sqrt{\det \mathbf{g}_d}} \Big|_{\mathbf{d}=\mathbf{f}(\mathbf{m})} , \quad (45)$$

where $\mathbf{F} = \mathbf{F}(\mathbf{m})$ is the matrix of partial derivatives, with components $\mathbf{F}_{i\alpha} = \partial f_i / \partial m_\alpha$, where $\mathbf{g}_m$ is the metric in the model parameter space $\mathcal{M}$ and where $\mathbf{g}_d$ is the metric in the data space $\mathcal{D}$.

Example 8. Quite often, $\rho(\mathbf{m}, \mathbf{d}) = \rho_m(\mathbf{m}) \rho_d(\mathbf{d})$. Then, Eq. (45) can be written

$$\sigma_m(\mathbf{m}) = k \rho_m(\mathbf{m}) \left(\frac{\rho_d(\mathbf{d})}{\sqrt{\det \mathbf{g}_m}} \frac{\sqrt{\det(\mathbf{g}_m + \mathbf{F}^T \mathbf{g}_d \mathbf{F})}}{\sqrt{\det \mathbf{g}_m}} \right) \Big|_{\mathbf{d}=\mathbf{f}(\mathbf{m})} . \quad (46)$$

Example 9. If $\mathbf{g}_m(\mathbf{m}) = \text{constant}$ and $\mathbf{g}_d(\mathbf{d}) = \text{constant}$, and the nonlinearities are weak ($\mathbf{F}(\mathbf{m}) = \text{constant}$), then Eq. (46) reduces to

$$\sigma_m(\mathbf{m}) = k \rho_m(\mathbf{m}) \frac{\rho_d(\mathbf{d})}{\mu_d(\mathbf{d})} \Big|_{\mathbf{d}=\mathbf{f}(\mathbf{m})} , \quad (47)$$

where we have used $\mu_d(\mathbf{d}) = k \sqrt{\det \mathbf{g}_d(\mathbf{d})}$ (see Rule 2).

Example 10. We examine here the simplification that we arrive at when assuming that the ‘input’ probability densities are Gaussian:

$$\rho_m(\mathbf{m}) = k \exp \left(-\frac{1}{2} (\mathbf{m} - \mathbf{m}_{\text{prior}})^t \mathbf{C}_M^{-1} (\mathbf{m} - \mathbf{m}_{\text{prior}}) \right) \quad (48)$$

$$\rho_d(\mathbf{d}) = k \exp \left(-\frac{1}{2} (\mathbf{d} - \mathbf{d}_{\text{obs}})^t \mathbf{C}_D^{-1} (\mathbf{d} - \mathbf{d}_{\text{obs}}) \right) . \quad (49)$$

In this circumstance, quite often, it is the covariance operators $\mathbf{C}_M$ and $\mathbf{C}_D$ that are used to define the metrics over the spaces $\mathcal{M}$ and $\mathcal{D}$. Then, $\mathbf{g}_m = \mathbf{C}_M^{-1}$ and $\mathbf{g}_d = \mathbf{C}_D^{-1}$. Grouping some of the constant factors in the factor k , Eq. (45) becomes here

$$\begin{aligned} \sigma_m(\mathbf{m}) = k \exp \left[-\frac{1}{2} \left((\mathbf{m} - \mathbf{m}_{\text{prior}})^t \mathbf{C}_M^{-1} (\mathbf{m} - \mathbf{m}_{\text{prior}}) \right. \right. \\ \left. \left. + (\mathbf{f}(\mathbf{m}) - \mathbf{d}_{\text{obs}})^t \mathbf{C}_D^{-1} (\mathbf{f}(\mathbf{m}) - \mathbf{d}_{\text{obs}}) \right) \right] \\ \times \frac{\sqrt{\det(\mathbf{C}_M^{-1} + \mathbf{F}^T(\mathbf{m}) \mathbf{C}_D^{-1} \mathbf{F}(\mathbf{m}))}}{\sqrt{\det \mathbf{C}_M^{-1}}} \end{aligned} \quad (50)$$

(the constant factor $\sqrt{\det \mathbf{C}_M^{-1}}$ has been left for subsequent simplifications). Defining the misfit

$$S(\mathbf{m}) = -2 \log \frac{\sigma_m(\mathbf{m})}{\sigma_0} , \quad (51)$$

where σ_0 is an arbitrary value of $\sigma_m(\mathbf{m})$, gives, up to an additive constant,

$$S(\mathbf{m}) = S_1(\mathbf{m}) - S_2(\mathbf{m}) , \quad (52)$$

where $S_1(\mathbf{m})$ is the usual least-squares misfit function

$$S_1(\mathbf{m}) = (\mathbf{m} - \mathbf{m}_{\text{prior}})^t \mathbf{C}_M^{-1} (\mathbf{m} - \mathbf{m}_{\text{prior}}) + (\mathbf{f}(\mathbf{m}) - \mathbf{d}_{\text{obs}})^t \mathbf{C}_D^{-1} (\mathbf{f}(\mathbf{m}) - \mathbf{d}_{\text{obs}}) \quad (53)$$

and where¹⁴

$$S_2(\mathbf{m}) = \log \det (\mathbf{I} + \mathbf{C}_M \mathbf{F}^t(\mathbf{m}) \mathbf{C}_D^{-1} \mathbf{F}(\mathbf{m})) . \quad (54)$$

Example 11. If, in the context of Example 10, we have¹⁵ $\mathbf{C}_M \mathbf{F}^t \mathbf{C}_D^{-1} \mathbf{F} \ll \mathbf{I}$, we can use the low order approximation for $S_2(\mathbf{m})$, that is¹⁶

$$S_2(\mathbf{m}) \approx \text{trace } \mathbf{C}_M \mathbf{F}^t(\mathbf{m}) \mathbf{C}_D^{-1} \mathbf{F}(\mathbf{m}) . \quad (55)$$

Example 12. If in the context of Example 10 we assume that the nonlinearities are weak, then the matrix of partial derivatives $\mathbf{F}$ is approximately constant, and Eq. (50) simplifies to

$$\sigma_m(\mathbf{m}) = k \exp \left[-\frac{1}{2} \left((\mathbf{m} - \mathbf{m}_{\text{prior}})^t \mathbf{C}_M^{-1} (\mathbf{m} - \mathbf{m}_{\text{prior}}) + (\mathbf{f}(\mathbf{m}) - \mathbf{d}_{\text{obs}})^t \mathbf{C}_D^{-1} (\mathbf{f}(\mathbf{m}) - \mathbf{d}_{\text{obs}}) \right) \right] , \quad (56)$$

and the function $S_2(\mathbf{m})$ is just a constant.

Example 13. If the ‘relation solving the forward problem’ $\mathbf{d} = \mathbf{f}(\mathbf{m})$ happens to be a linear relation, $\mathbf{d} = \mathbf{F} \mathbf{m}$, then one gets the standard equations for linear problems (see Appendix F).

Example 14. We examine here the simplifications that we arrive at when assuming that the ‘input’ probability densities are Laplacian:

$$\rho_m(\mathbf{m}) = k \exp \left(-\sum_{\alpha} \frac{|m^{\alpha} - m_{\text{prior}}^{\alpha}|}{\sigma_{\alpha}} \right) \quad (57)$$

$$\rho_d(\mathbf{d}) = k \exp \left(-\sum_i \frac{|d^i - d_{\text{obs}}^i|}{\sigma_i} \right) . \quad (58)$$

Equation (45) becomes here

$$\sigma_m(\mathbf{m}) = k \exp \left[-\left(\sum_{\alpha} \frac{|m^{\alpha} - m_{\text{prior}}^{\alpha}|}{\sigma_{\alpha}} + \sum_i \frac{|f^i(\mathbf{m}) - d_{\text{obs}}^i|}{\sigma_i} \right) \right] \Psi(\mathbf{m}) , \quad (59)$$

where $\Psi(\mathbf{m})$ is a complex term containing, in particular, the matrix of partial derivatives $\mathbf{F}$. If this term is approximately constant (weak nonlinearities, constant metrics), then

$$\sigma_m(\mathbf{m}) = k \exp \left[-\left(\sum_{\alpha} \frac{|m^{\alpha} - m_{\text{prior}}^{\alpha}|}{\sigma_{\alpha}} + \sum_i \frac{|f^i(\mathbf{m}) - d_{\text{obs}}^i|}{\sigma_i} \right) \right] . \quad (60)$$

The formulas in the examples above give expressions that contain analytic parts (like the square roots containing the matrix of partial derivatives $\mathbf{F}$). What we write as $\mathbf{d} = \mathbf{f}(\mathbf{m})$ may sometimes correspond to an explicit expression; sometimes it may correspond to the solution of an implicit equation.¹⁷ Should $\mathbf{d} = \mathbf{f}(\mathbf{m})$ be an explicit expression, and should the ‘prior probability densities’ $\rho_m(\mathbf{m})$ and $\rho_d(\mathbf{d})$ (or the joint $\rho(\mathbf{m}, \mathbf{d})$) also be given by explicit expressions (as when we have Gaussian probability densities), then the formulas of this section would give explicit expressions for the posterior probability density $\sigma_m(\mathbf{m})$.

If the relation $\mathbf{d} = \mathbf{f}(\mathbf{m})$ is a linear relation, then the expression giving $\sigma_m(\mathbf{m})$ can sometimes be simplified easily (as with the linear Gaussian case to be examined below). More often than not the relation $\mathbf{d} = \mathbf{f}(\mathbf{m})$ is a complex nonlinear relation, and the expression we are left with for $\sigma_m(\mathbf{m})$ is explicit, but complex.

Once the probability density $\sigma_m(\mathbf{m})$ has been defined, there are different ways of ‘using’ it. If the ‘model space’ $\mathcal{M}$ has a small number of dimensions (say between one and four) the values of $\sigma_m(\mathbf{m})$ can be computed at every point of a grid and a graphical representation of $\sigma_m(\mathbf{m})$ can be attempted. A visual inspection of such a representation is usually worth a thousand ‘estimators’ (central estimators or estimators of dispersion). But, of course, if the values of $\sigma_m(\mathbf{m})$ are known at all points where $\sigma_m(\mathbf{m})$ has a significant value, these estimators can also be computed.

If the ‘model space’ $\mathcal{M}$ has a large number of dimensions (say from five to many millions or billions), then an exhaustive exploration of the space is not possible, and we must turn to Monte Carlo sampling methods to extract information from $\sigma_m(\mathbf{m})$. We discuss the application of Monte Carlo methods to inverse problems, and optimization techniques, in Section 6 and 7, respectively.

4.6 Physical Laws as Probabilistic Correlations

4.6.1 Physical Laws

We return here to the general case where it is not assumed that the total space $(\mathcal{M}, \mathcal{D})$ is the Cartesian product of two spaces.

In Section 4.5 we have examined the situation where the physical correlation between the parameters of the

problem are expressed using an exact, analytic expression $\mathbf{d} = \mathbf{g}(\mathbf{m})$. In this case, the notion of conditional probability density has been used to combine the ‘physical theory’ with the ‘data’ and the ‘a priori information’ on model parameters.

But, we have seen that in order to properly define the notion of conditional probability density, it has been necessary to introduce a metric over the space, and to take a limit using the metric of the space. This is equivalent to put some ‘thickness’ around the theoretical relation $\mathbf{d} = \mathbf{g}(\mathbf{m})$, and to take the limit when the thickness tends to zero.

But actual theories have uncertainties, and, for more generality, it is better to explicitly introduce these uncertainties. Assume, then, that the physical correlations between the model parameters $\mathbf{m}$ and the data parameters $\mathbf{d}$ are not represented by an analytical expression like $\mathbf{d} = \mathbf{f}(\mathbf{m})$ but by a probability density

$$\vartheta(\mathbf{m}, \mathbf{d}). \quad (61)$$

Example: Realistic ‘Uncertainty Bars’ around a Functional Relation. In the approximation of a constant gravity field, with acceleration $\mathbf{g}$, the position at time t of an apple in free fall is $\mathbf{r}(t) = \mathbf{r}_0 + \mathbf{v}_0 t + \frac{1}{2} \mathbf{g} t^2$, where $\mathbf{r}_0$ and $\mathbf{v}_0$ are, respectively, the position and velocity of the object at time $t=0$. More simply, if the movement is 1D,

$$x(t) = x_0 + v_0 t + \frac{1}{2} g t^2. \quad (62)$$

Of course, for many reasons this equation can never be exact: air friction, wind effects, inhomogeneity of the gravity field, effects of the Earth rotation, forces from the Sun and the Moon (not to mention Pluto), relativity (special and general), and so on.

It is not a trivial task, given very careful experimental conditions, to estimate the size of the leading uncertainty. Although one might think of an equation $x = x(t)$ as a line, infinitely thin, there will always be sources of uncertainty (at least due to the unknown limits of validity of general relativity): looking at the line with a magnifying glass should reveal a fuzzy object of finite thickness. As a simple example, let us examine here the mathematical object we arrive at when assuming that the leading sources of uncertainty in the relation $x = x(t)$ are the uncertainties in the initial position and velocity of the falling apple. Let us assume that:

- the initial position of the apple is random, with a Gaussian distribution centered at x_0 , and with standard deviation σ_x ;
- the initial velocity of the apple is random, with a Gaussian distribution centered at v_0 , and with standard deviation σ_v .

Then it can be shown that at a given time t , the possible positions of the apple are random, with probability density

$$\vartheta(x|t) = \frac{1}{\sqrt{2\pi}\sqrt{\sigma_x^2 + \sigma_v^2 t^2}} \times \exp\left(-\frac{1}{2} \frac{(x - (x_0 + v_0 t + \frac{1}{2} g t^2))^2}{\sigma_x^2 + \sigma_v^2 t^2}\right). \quad (63)$$

This is obviously a conditional probability density for x , given t . Should we have any reason to choose some marginal probability density $\vartheta_t(t)$, then, the ‘law’ for the fall of the apple would be

$$\vartheta(x, t) = \vartheta(x|t) \vartheta_t(t). \quad (64)$$

See Appendix C for more details.

4.6.2 Inverse Problems

We have seen that the result of measurements can be represented by a probability density $\rho_d(\mathbf{d})$ in the data space. We have also seen that the a priori information on the model parameters can be represented by another probability density $\rho_m(\mathbf{m})$ in the model space. When we talk about ‘measurements’ and about ‘a priori information on model parameters,’ we usually mean that we have a joint probability density in the $(\mathcal{M}, \mathcal{D})$ space, that is $\rho(\mathbf{m}, \mathbf{d}) = \rho_m(\mathbf{m}) \rho_d(\mathbf{d})$. Let us consider the more general situation where for the whole set of parameters $(\mathcal{M}, \mathcal{D})$ we have some information that can be represented by a joint probability density $\rho(\mathbf{m}, \mathbf{d})$. Having well in mind the interpretation of this information, let us use the simple term ‘experimental information’ for it:

$$\rho(\mathbf{m}, \mathbf{d}) \quad (\text{experimental information}). \quad (65)$$

We have also seen that we have information coming from physical theories, that predict correlations between the parameters, and it has been argued that a probabilistic description of these correlations is well adapted to the resolution of inverse problems.¹⁸ Let $\vartheta(\mathbf{m}, \mathbf{d})$ be the probability density representing this ‘theoretical information’:

$$\vartheta(\mathbf{m}, \mathbf{d}) \quad (\text{theoretical information}). \quad (66)$$

A quite fundamental assumption is that in all the spaces we consider, there is a notion of volume that allows us to give meaning to the notion of a ‘homogeneous probability distribution’ over the space. The corresponding probability density is not constant, but is proportional to the volume element of the space (see Section 2.2):

$$\mu(\mathbf{m}, \mathbf{d}) \quad (\text{homogeneous probability distribution}). \quad (67)$$

Finally, we have seen examples suggesting that the conjunction of the experimental information with the theoretical information corresponds exactly to the AND operation defined

over the probability densities, to obtain the ‘conjunction of information,’ as represented by the probability density

$$\sigma(\mathbf{m}, \mathbf{d}) = k \frac{\rho(\mathbf{m}, \mathbf{d}) \vartheta(\mathbf{m}, \mathbf{d})}{\mu(\mathbf{m}, \mathbf{d})} \quad (68)$$

(conjunction of information),

with marginal probability densities

$$\sigma_m(\mathbf{m}) = \int_{\mathcal{D}} d\mathbf{d} \sigma(\mathbf{m}, \mathbf{d}) ; \quad \sigma_d(\mathbf{d}) = \int_{\mathcal{M}} d\mathbf{m} \sigma(\mathbf{m}, \mathbf{d}) . \quad (69)$$

Example 15. We may assume that the physical correlations between the parameters $\mathbf{m}$ and $\mathbf{d}$ are of the form

$$\vartheta(\mathbf{m}, \mathbf{d}) = \vartheta_{D|M}(\mathbf{d}|\mathbf{m}) \vartheta_M(\mathbf{m}) , \quad (70)$$

this expressing that a ‘physical theory’ gives, on the one hand, the conditional probability for $\mathbf{d}$, given $\mathbf{m}$, and, on the other hand, the marginal probability density for $\mathbf{m}$. See Appendix C for more details.

Example 16. Many applications concern the special situation where we have

$$\mu(\mathbf{m}, \mathbf{d}) = \mu_m(\mathbf{m}) \mu_d(\mathbf{d}) ; \quad \rho(\mathbf{m}, \mathbf{d}) = \rho_m(\mathbf{m}) \rho_d(\mathbf{d}) . \quad (71)$$

In this case, Eqs. (68) and (69) give

$$\sigma_m(\mathbf{m}) = k \frac{\rho_m(\mathbf{m})}{\mu_m(\mathbf{m})} \int_{\mathcal{D}} d\mathbf{d} \frac{\rho_d(\mathbf{d}) \vartheta(\mathbf{m}, \mathbf{d})}{\mu_d(\mathbf{d})} . \quad (72)$$

If Eq. (70) holds, then

$$\sigma_m(\mathbf{m}) = k \rho_m(\mathbf{m}) \frac{\vartheta_m(\mathbf{m})}{\mu_m(\mathbf{m})} \int_{\mathcal{D}} d\mathbf{d} \frac{\rho_d(\mathbf{d}) \vartheta_{D|M}(\mathbf{d}|\mathbf{m})}{\mu_d(\mathbf{d})} . \quad (73)$$

Finally, if the simplification $\vartheta_M(\mathbf{m}) = \mu_m(\mathbf{m})$ arises (see Appendix C for an illustration), then

$$\sigma_m(\mathbf{m}) = k \rho_m(\mathbf{m}) \int_{\mathcal{D}} d\mathbf{d} \frac{\rho_d(\mathbf{d}) \vartheta(\mathbf{d}|\mathbf{m})}{\mu_d(\mathbf{d})} . \quad (74)$$

Example 17. In the context of the previous example, assume that observational uncertainties are Gaussian:

$$\rho_d(\mathbf{d}) = k \exp \left(-\frac{1}{2} (\mathbf{d} - \mathbf{d}_{\text{obs}})^t \mathbf{C}_D^{-1} (\mathbf{d} - \mathbf{d}_{\text{obs}}) \right) . \quad (75)$$

Note that the limit for infinite variances gives the homogeneous probability density $\mu_d(\mathbf{d}) = k$. Furthermore,

assume that uncertainties in the physical law are also Gaussian:

$$\vartheta(\mathbf{d}|\mathbf{m}) = k \exp \left(-\frac{1}{2} (\mathbf{d} - \mathbf{f}(\mathbf{m}))^t \mathbf{C}_T^{-1} (\mathbf{d} - \mathbf{f}(\mathbf{m})) \right) . \quad (76)$$

Here ‘the physical theory says’ that the data values must be ‘close’ to the ‘computed values’ $\mathbf{f}(\mathbf{m})$, with a notion of closeness defined by the ‘theoretical covariance matrix’ $\mathbf{C}_T$. As demonstrated in Tarantola (1987, p. 158), the integral in Eq. (74) can be analytically evaluated, and gives

$$\begin{aligned} & \int_{\mathcal{D}} d\mathbf{d} \frac{\rho_d(\mathbf{d}) \vartheta(\mathbf{d}|\mathbf{m})}{\mu_d(\mathbf{d})} \\ &= k \exp \left(-\frac{1}{2} (\mathbf{f}(\mathbf{m}) - \mathbf{d}_{\text{obs}})^t (\mathbf{C}_D + \mathbf{C}_T)^{-1} (\mathbf{f}(\mathbf{m}) - \mathbf{d}_{\text{obs}}) \right) . \end{aligned} \quad (77)$$

This shows that when using the Gaussian probabilistic model, observational and theoretical uncertainties combine through addition of the respective covariance operators (a nontrivial result).

Example 18. In the ‘Galilean law’ example developed in Section 4.61, we described the correlation between the position x and the time t of a free falling object through a probability density $\vartheta(x, t)$. This law says that falling objects describe, approximately, a space–time parabola. Assume that in a particular experiment the falling object explodes at some point of its space–time trajectory. A plain measurement of the coordinates (x, t) of the event gives the probability density $\rho(x, t)$. By ‘plain measurement’ we mean here that we have used a measurement technique that is not taking into account the particular parabolic character of the fall (i.e., the measurement is designed to work identically for any sort of trajectory). The conjunction of the physical law $\vartheta(x, t)$ and the experimental result $\rho(x, t)$, using expression (68), gives

$$\sigma(x, t) = k \frac{\rho(x, t) \vartheta(x, t)}{\mu(x, t)} , \quad (78)$$

where, as the coordinates (x, t) are ‘Cartesian,’ $\mu(x, t) = k$. Taking the explicit expression given for $\vartheta(x, t)$ in Eqs. (63) and (64), with $\vartheta_t(t) = k$,

$$\begin{aligned} \vartheta(x, t) &= \frac{1}{\sqrt{2\pi} \sqrt{\sigma_x^2 + \sigma_v^2 t^2}} \\ &\times \exp \left(-\frac{1}{2} \frac{(x - (x_0 + v_0 t + \frac{1}{2} g t^2))^2}{\sigma_x^2 + \sigma_v^2 t^2} \right) , \end{aligned} \quad (79)$$

FIGURE 7 This figure has been made with the numerical values mentioned in Figure 17 (see Appendix C) with, in addition, $x_{\text{obs}} = 5.0$ m, $\Sigma_x = 4.0$ m, $t_{\text{obs}} = 2.0$ sec and $\Sigma_t = 0.75$ sec.

and assuming the Gaussian form¹⁹ for $\rho(x, t)$,

$$\begin{aligned} \rho(x, t) &= \rho_x(x) \rho_t(t) \\ &= k \exp\left(-\frac{1}{2} \frac{(x - x_{\text{obs}})^2}{\Sigma_x^2}\right) \exp\left(-\frac{1}{2} \frac{(t - t_{\text{obs}})^2}{\Sigma_t^2}\right) \end{aligned} \quad (80)$$

we obtain the combined probability density

$$\begin{aligned} \sigma(x, t) &= \frac{k}{\sqrt{\sigma_x^2 + \sigma_v^2 t^2}} \exp\left(-\frac{1}{2} \left(\frac{(x - x_{\text{obs}})^2}{\Sigma_x^2} + \frac{(t - t_{\text{obs}})^2}{\Sigma_t^2} \right. \right. \\ &\quad \left. \left. + \frac{(x - (x_0 + v_0 t + \frac{1}{2} g t^2))^2}{\sigma_x^2 + \sigma_v^2 t^2} \right) \right). \end{aligned} \quad (81)$$

Figure 7 illustrates the three probability densities $\vartheta(x, t)$, $\rho(x, t)$, and $\sigma(x, t)$. See Appendix C for a more detailed examination of this problem.

5. Solving Inverse Problems (I): Examination of the Probability Density

The next two sections deal with Monte Carlo and optimization methods. The implementation of these methods takes some programming effort that is not required when we face problems with fewer degrees of freedom (say, between one and five).

When we have a small number of parameters we should directly ‘plot’ the probability density.

In Appendix K the problem of estimation of a seismic hypocenter is treated, and it is shown there that the examination of the probability density for the location of the hypocenter offers a much better possibility for analysis than any other method.

6. Solving Inverse Problems (II): Monte Carlo Methods

6.1 Basic Equations

The starting point could be the explicit expression (Eq. (46)) for $\sigma_m(\mathbf{m})$ given in Section 4.5.2:

$$\sigma_m(\mathbf{m}) = k \rho_m(\mathbf{m}) L(\mathbf{m}). \quad (82)$$

where

$$L(\mathbf{m}) = \left(\frac{\rho_d(\mathbf{d})}{\sqrt{\det \mathbf{g}_d(\mathbf{d})}} \frac{\sqrt{\det(\mathbf{g}_m(\mathbf{m}) + \mathbf{F}^T(\mathbf{m}) \mathbf{g}_d(\mathbf{d}) \mathbf{F}(\mathbf{m}))}}{\sqrt{\det \mathbf{g}_m(\mathbf{m})}} \right) \Big|_{\mathbf{d}=\mathbf{f}(\mathbf{m})}. \quad (83)$$

In this expression the matrix of partial derivatives $\mathbf{F} = \mathbf{F}(\mathbf{m})$, with components $D_{i\alpha} = \partial f_i / \partial m_\alpha$, appears. The ‘slope’ $\mathbf{F}$ enters here because the steeper the slope for a given $\mathbf{m}$, the greater the accumulation of points we will have with this particular $\mathbf{m}$. This is because we use explicitly the analytic expression $\mathbf{d} = \mathbf{f}(\mathbf{m})$. One should realize that using the more general approach based on Eq. (68) of Section 4.6.2, the effect is automatically accounted for, and there is no need to explicitly consider the partial derivatives.

Equation (82) has the standard form of a conjunction of two probability densities, and is therefore ready to be integrated in a Metropolis algorithm. But one should note that, contrary to many ‘nonlinear’ formulations of inverse problems, the partial derivatives $\mathbf{F}$ are needed even if we use a Monte Carlo method.

In some weakly nonlinear problems, we have $\mathbf{F}^T(\mathbf{m}) \mathbf{g}_d(\mathbf{d}) \mathbf{F}(\mathbf{m}) \ll \mathbf{g}_m(\mathbf{m})$, and then Eq. (83) becomes

$$L(\mathbf{m}) = \frac{\rho_d(\mathbf{d})}{\mu_d(\mathbf{d})} \Big|_{\mathbf{d}=\mathbf{f}(\mathbf{m})}, \quad (84)$$

where we have used $\mu_d(\mathbf{d}) = k \sqrt{\det \mathbf{g}_d(\mathbf{d})}$ (see Rule 2).

This expression is also ready for use in the Metropolis algorithm. In this way, sampling of the prior $\rho_m(\mathbf{m})$ is modified into a sampling of the posterior $\sigma_m(\mathbf{m})$, and the Metropolis Rule uses the ‘likelihood function’ $L(\mathbf{m})$ to calculate acceptance probabilities.

6.2 Sampling the Homogeneous Probability Distribution

If we do not have an algorithm that samples the prior probability density directly, the first step in a Monte Carlo analysis of an inverse problem is to design a random walk that samples the model space according to the homogeneous probability distribution $\mu_m(\mathbf{m})$. In some cases this is easy, but in other cases only an algorithm (a *primeval random walk*) that samples an arbitrary (possibly constant) probability density $\psi(\mathbf{m}) \neq \mu_m(\mathbf{m})$ is available. Then the Metropolis rule can be used to modify $\psi(\mathbf{m})$ into $\mu_m(\mathbf{m})$ (see Section 3.4). This way of generating samples from $\mu_m(\mathbf{m})$ is efficient if $\psi(\mathbf{m})$ is close to $\mu_m(\mathbf{m})$, otherwise it may be very inefficient.

Once $\mu(\mathbf{m})$ can be sampled, the Metropolis Rule allows us to modify this sampling into an algorithm that samples the prior.

6.3 Sampling the Prior Probability Distribution

The first step in the Monte Carlo analysis is to temporarily ‘switch off’ the comparison between computed and observed data, thereby generating samples of the prior probability density. This allows us to verify statistically that the algorithm is working correctly, and it allows us to understand the prior information we are using. We will refer to a large collection of models representing the prior probability distribution as the ‘prior movie’ (in a computer screen, when the models are displayed one after the other, we have a ‘movie’). The more models present in this movie, the more accurate the representation of the prior probability density.

6.4 Sampling the Posterior Probability Distribution

If we now switch on the comparison between computed and observed data using, e.g., the Metropolis rule for the actual Eq. (82), the random walk sampling the prior distribution is modified into a walk sampling the posterior distribution.

Since data rarely put strong constraints on the Earth, the ‘posterior movie’ typically shows that many different models are possible. But even though the models in the posterior movie may be quite different, all of them predict data that, within experimental uncertainties, are models with high likelihood. In other words, we must accept that data alone cannot have a preferred model.

The posterior movie allows us to perform a proper resolution analysis that helps us to choose between different interpretations of a given data set. Using the movie we can answer complicated questions about the correlations between several model parameters. To answer such questions, we can view the posterior movie and try to discover structure that is well resolved by data. Such structure will appear as ‘persistent’ in the posterior movie.

The ‘movie’ can be used to answer quite complicated questions. For instance, to answer the question ‘Which is the probability that the Earth has this special characteristic, but not having this other special characteristic?’ we can just count the number n of models (samples) satisfying the criterion, and the probability is $P = n/m$, where m is the total number of samples.

Once this ‘movie’ is generated, it is, of course, possible to represent the 1D or 2D marginal probability densities for all or for some selected parameters: it is enough to concentrate one’s attention on those selected parameters in each of the samples generated. Those marginal probability densities may have some pathologies (like being multimodal, or having infinite dispersions), but those are the general characteristics of the joint probability density. Our numerical experience shows that these marginals are, quite often, ‘stable’ objects, in the sense that they can be accurately determined with only a small number of samples.

If the marginals are, essentially, beautiful bell-shaped distributions, then, one may proceed to merely computing mean values and standard deviations (or median values and mean deviations), using each of the samples and the elementary statistical formulas.

Another, more traditional, way of investigating resolution is to calculate covariances and higher-order moments. For this we need to evaluate integrals of the form

$$R_f = \int_{\mathcal{A}} d\mathbf{m} f(\mathbf{m}) \sigma_m(\mathbf{m}) \quad (85)$$

where $f(\mathbf{m})$ is a given function of the model parameters and $\mathcal{A}$ is an event in the model space $\mathcal{M}$ containing the models we are interested in. For instance,

$$\mathcal{A} = \{\mathbf{m} \mid \text{a given range of parameters in } \mathbf{m} \text{ is } \textit{cyclic}\} . \quad (86)$$

In the special case when $\mathcal{A} = \mathcal{M}$ is the entire model space, and $f(\mathbf{m}) = m_i$, the R_f in Eq. (85) equals the mean $\langle m_i \rangle$ of the i th model parameter m_i . If $f(\mathbf{m}) = (m_i - \langle m_i \rangle)(m_j - \langle m_j \rangle)$, R_f becomes the covariance between the i th and j th model parameters. Typically, in the general inverse problem we cannot evaluate the integral in Eq. (85) analytically because we have no analytical expression for $\sigma(\mathbf{m})$. However, from the samples of the posterior

movie $\mathbf{m}_1, \dots, \mathbf{m}_n$ we can approximate R_f by the simple average

$$R_f \approx \frac{1}{\text{total number of models}} \sum_{\{\mathbf{m}_i \in \mathcal{A}\}} f(\mathbf{m}_i) . \quad (87)$$

7. Solving Inverse Problems (III): Deterministic Methods

As we have seen, the solution of an inverse problem essentially consists of a probability distribution over the space of all possible models of the physical system under study. In general, this ‘model space’ is high-dimensional, and the only general way to explore it is by using the Monte Carlo methods developed in Section 3.

If the probability distributions are ‘bell-shaped’ (i.e., if they look like a Gaussian or like a generalized Gaussian), then one may simplify the problem by calculating only the point around which the probability is maximum, with an approximate estimation of the variances and covariances. This is the problem addressed in this section. Among the many methods available to obtain the point at which a scalar function reaches its maximum value (relaxation methods, linear programming techniques, etc.) we limit our scope here to the methods using the gradient of the function, which we assume can be computed analytically, or at least, numerically. For more general methods, the reader may have a look at Fletcher (1980, 1981), Powell (1981), Scales (1985), Tarantola (1987) or Scales *et al.* (1992).

7.1 Maximum Likelihood Point

Let us consider a space $\mathcal{X}$, with a volume element dV defined. If the coordinates $\mathbf{x} \equiv \{x^1, x^2, \dots, x^n\}$ are chosen over the space, the volume element has an expression $dV(\mathbf{x}) = v(\mathbf{x}) d\mathbf{x}$, and each probability distribution over $\mathcal{X}$ can be represented by a probability density $f(\mathbf{x})$. For any fixed small volume ΔV we can search for the point $\mathbf{x}_{\text{ML}}$ such that the probability dP of the small volume, when centered around $\mathbf{x}_{\text{ML}}$, attains a maximum. In the limit $\Delta V \rightarrow 0$ this defines the *maximum likelihood point*. The maximum likelihood point may be unique (if the probability distribution is unimodal), may be degenerate (if the probability distribution is ‘chevron-shaped’), or may be multiple (as when we have the sum of a few bell-shaped functions).

The maximum likelihood point is *not* the point at which the probability density is maximum. Our definition implies that a maximum must be attained by the ratio between the probability density and the function $v(\mathbf{x})$ defining the volume element:²⁰

$$\mathbf{x} = \mathbf{x}_{\text{ML}} \iff F(\mathbf{x}) = \frac{f(\mathbf{x})}{v(\mathbf{x})} \quad (\text{maximum}) . \quad (88)$$

As the homogeneous probability density is $\mu(\mathbf{x}) = k v(\mathbf{x})$ (see Rule 2), we can equivalently define the maximum likelihood point by the condition

$$\mathbf{x} = \mathbf{x}_{\text{ML}} \iff \frac{f(\mathbf{x})}{\mu(\mathbf{x})} \quad (\text{maximum}) . \quad (89)$$

The point at which a probability density has its maximum is, in general, not $\mathbf{x}_{\text{ML}}$. In fact, the maximum of a probability density does not correspond to an intrinsic definition of a point: a change of coordinates $\mathbf{x} \mapsto \mathbf{y} = \psi(\mathbf{x})$ would change the probability density $f(\mathbf{x})$ into the probability density $g(\mathbf{y})$ (obtained using the Jacobian rule), but the point of the space at which $f(\mathbf{x})$ is maximum is not the same as the point of the space where $g(\mathbf{y})$ is maximum (unless the change of variables is linear). This contrasts with the maximum likelihood point, as defined by Eq. (89), which is an intrinsically defined point: no matter which coordinates we use in the computation we always obtain the same point of the space.

7.2 Misfit

One of the goals here is to develop gradient-based methods for obtaining the maximum of $F(\mathbf{x}) = f(\mathbf{x})/\mu(\mathbf{x})$. As a quite general rule, gradient-based methods perform quite poorly for (bell-shaped) probability distributions, as when one is far from the maximum the probability densities tend to be quite flat, and it is difficult to get, reliably, the direction of steepest ascent. Taking a logarithm transforms a bell-shaped distribution into a paraboloid-shaped distribution on which gradient methods work well.

The logarithmic volumetric probability, or *misfit*, is defined as $S(\mathbf{x}) = -\log(F(\mathbf{x})/F_0)$, where p' and F_0 are two constants, and is given by

$$S(\mathbf{x}) = -\log \frac{f(\mathbf{x})}{\mu(\mathbf{x})} . \quad (90)$$

The problem of maximization of the (typically) bell-shaped function $f(\mathbf{x})/\mu(\mathbf{x})$ has been transformed into the problem of minimization of the (typically) paraboloid-shaped function $S(\mathbf{x})$:

$$\mathbf{x} = \mathbf{x}_{\text{ML}} \iff S(\mathbf{x}) \quad (\text{minimum}) . \quad (91)$$

Example 19. The conjunction $\sigma(\mathbf{x})$ of two probability densities $\rho(\mathbf{x})$ and $\vartheta(\mathbf{x})$ was defined (Eq. (13)) as

$$\sigma(\mathbf{x}) = p \frac{\rho(\mathbf{x}) \vartheta(\mathbf{x})}{\mu(\mathbf{x})} . \quad (92)$$

Then,

$$S(\mathbf{x}) = S_\rho(\mathbf{x}) + S_\vartheta(\mathbf{x}) , \quad (93)$$

where

$$S_\rho(\mathbf{x}) = -\log \frac{\rho(\mathbf{x})}{\mu(\mathbf{x})}; \quad S_\vartheta(\mathbf{x}) = -\log \frac{\vartheta(\mathbf{x})}{\mu(\mathbf{x})}. \quad (94)$$

Example 20. In the context of Gaussian distributions we have found the probability density (see Example 12)

$$\sigma_m(\mathbf{m}) = k \exp \left[-\frac{1}{2} \left((\mathbf{m} - \mathbf{m}_{\text{prior}})^t \mathbf{C}_M^{-1} (\mathbf{m} - \mathbf{m}_{\text{prior}}) + (\mathbf{f}(\mathbf{m}) - \mathbf{d}_{\text{obs}})^t \mathbf{C}_D^{-1} (\mathbf{f}(\mathbf{m}) - \mathbf{d}_{\text{obs}}) \right) \right]. \quad (95)$$

The limit of this distribution for infinite variances is a constant, so in this case $\mu_m(\mathbf{m}) = k$. The misfit function $S(\mathbf{m}) = -\log(\sigma_m(\mathbf{m})/\mu_m(\mathbf{m}))$ is then given by

$$2S(\mathbf{m}) = (\mathbf{m} - \mathbf{m}_{\text{prior}})^t \mathbf{C}_M^{-1} (\mathbf{m} - \mathbf{m}_{\text{prior}}) + (\mathbf{f}(\mathbf{m}) - \mathbf{d}_{\text{obs}})^t \mathbf{C}_D^{-1} (\mathbf{f}(\mathbf{m}) - \mathbf{d}_{\text{obs}}). \quad (96)$$

The reader should remember that this misfit function is valid only for weakly nonlinear problems (see Examples 10 and 12). The maximum likelihood model here is the one that minimizes the sum of squares (96). This corresponds to the least-squares criterion.

7.3 Gradient and Direction of Steepest Ascent

One must not consider as synonymous the notions of ‘gradient’ and ‘direction of steepest ascent.’ Consider, for instance, an *adimensional* misfit function²¹ $S(P, T)$ over a pressure P and a temperature T . Any sensible definition of the gradient of S will lead to an expression like

$$\text{grad } S = \begin{pmatrix} \frac{\partial S}{\partial P} \\ \frac{\partial S}{\partial T} \end{pmatrix} \quad (97)$$

and this by no means can be regarded as a ‘direction’ in the (P, T) space (for instance, the components of this ‘vector’ does not have the dimensions of pressure and temperature, but of inverse pressure and inverse temperature).

Mathematically speaking, the gradient of a function $S(\mathbf{x})$ at a point $\mathbf{x}_0$ is the linear function that is tangent to $S(\mathbf{x})$ at $\mathbf{x}_0$. This definition of gradient is consistent with the more elementary one, based on the use of the first-order expansion

$$S(\mathbf{x}_0 + \delta\mathbf{x}) = S(\mathbf{x}_0) + \hat{\mathbf{y}}_0^T \delta\mathbf{x} + \dots \quad (98)$$

Here $\hat{\mathbf{y}}_0$ is called the gradient of $S(\mathbf{x})$ at point $\mathbf{x}_0$. It is clear that $S(\mathbf{x}_0) + \hat{\mathbf{y}}_0^T \delta\mathbf{x}$ is a linear function, and that it is tangent to $S(\mathbf{x})$ at $\mathbf{x}_0$, so the two definitions are in fact

equivalent. Explicitly, the components of the gradient at point $\mathbf{x}_0$ are

$$(\hat{\mathbf{y}}_0)_p = \frac{\partial S}{\partial x^p}(\mathbf{x}_0). \quad (99)$$

Everybody is well trained in computing the gradient of a function (even if the interpretation of the result as a direction in the original space is wrong). How can we pass from the gradient to the direction of steepest ascent (a bona fide direction in the original space)? In fact, the gradient (at a given point) of a function defined over a given space $\mathcal{E}$ is an element of the dual of the space. To obtain a direction in $\mathcal{E}$ we must pass from the dual to the primal space. As usual, it is the metric of the space that maps the dual of the space into the space itself. So if $\mathbf{g}$ is the metric of the space where $S(\mathbf{x})$ is defined, and if $\hat{\mathbf{y}}$ is the gradient of S at a given point, the direction of steepest ascent is

$$\mathbf{y} = \mathbf{g}^{-1} \hat{\mathbf{y}}. \quad (100)$$

The direction of steepest ascent must be interpreted as follows: if we are at a point $\mathbf{x}$ of the space, we can consider a very small hypersphere around $\mathbf{x}_0$. The direction of steepest ascent points toward the point of the sphere at which $S(\mathbf{x})$ attains its maximum value.

Example 21. In the context of least squares, we consider a misfit function $S(\mathbf{m})$ and a covariance matrix $\mathbf{C}_M$. If $\hat{\mathbf{y}}_0$ is the gradient of S , at a point $\mathbf{x}_0$, and if we use $\mathbf{C}_M$ to define distances in the space, the direction of steepest ascent is

$$\mathbf{y}_0 = \mathbf{C}_M \hat{\mathbf{y}}_0. \quad (101)$$

7.4 The Steepest Descent Method

Consider that we have a probability distribution defined over an n -dimensional space $\mathcal{X}$. Having chosen the coordinates $\mathbf{x} \equiv \{x^1, x^2, \dots, x^n\}$ over the space, the probability distribution is represented by the probability density $f(\mathbf{x})$ whose homogeneous limit (in the sense developed in Section 2.2) is $\mu(\mathbf{x})$. We wish to calculate the coordinates $\mathbf{x}_{\text{ML}}$ of the maximum likelihood point. By definition (Eq. (89)),

$$\mathbf{x} = \mathbf{x}_{\text{ML}} \iff \frac{f(\mathbf{x})}{\mu(\mathbf{x})} \text{ (maximum)}, \quad (102)$$

that is,

$$\mathbf{x} = \mathbf{x}_{\text{ML}} \iff S(\mathbf{x}) \text{ (minimum)}, \quad (103)$$

where $S(\mathbf{x})$ is the misfit [Eq. (90)]

$$S(\mathbf{x}) = -k \log \frac{f(\mathbf{x})}{\mu(\mathbf{x})}. \quad (104)$$

Let us denote by $\hat{\mathbf{y}}(\mathbf{x}_k)$ the gradient of $S(\mathbf{x})$ at point $\mathbf{x}_k$, i.e. (Eq. (99)),

$$(\hat{\mathbf{y}}_0)_p = \frac{\partial S}{\partial x^p}(\mathbf{x}_0). \quad (105)$$

We have seen above that $\hat{\mathbf{y}}(\mathbf{x})$ should not be interpreted as a direction in the space $\mathcal{X}$ but as a direction in the dual space. The gradient can be converted into a direction using a metric $\mathbf{g}(\mathbf{x})$ over $\mathcal{X}$. In simple situations the metric $\mathbf{g}$ will be the one used to define the volume element of the space, i.e., we will have $\mu(\mathbf{x}) = k v(\mathbf{x}) = k \sqrt{\det \mathbf{g}(\mathbf{x})}$, but this is not a necessity, and iterative algorithms may be accelerated by astute introduction of ad-hoc metrics.

Given, then, the gradient $\hat{\mathbf{y}}(\mathbf{x}_k)$ (at some particular point $\mathbf{x}_k$) to any possible choice of metric $\mathbf{g}(\mathbf{x})$ we can define the direction of steepest ascent associated with the metric $\mathbf{g}$, by (Eq. (101))

$$\mathbf{y}(\mathbf{x}_k) = \mathbf{g}^{-1}(\mathbf{x}_k) \hat{\mathbf{y}}(\mathbf{x}_k). \quad (106)$$

The algorithm of steepest descent is an iterative algorithm passing from point $\mathbf{x}_k$ to point $\mathbf{x}_{k+1}$ by making a ‘small jump’ along the local direction of steepest descent,

$$\mathbf{x}_{k+1} = \mathbf{x}_k - \varepsilon_k \mathbf{g}_k^{-1} \hat{\mathbf{y}}_k, \quad (107)$$

where ε_k is an ad-hoc (real, positive) value adjusted to force the algorithm to converge rapidly (if ε_k is chosen too small, the convergence may be too slow; it is chosen too large, the algorithm may even diverge).

Many elementary presentations of the steepest descent algorithm just forget to include the metric $\mathbf{g}_k$ in expression (107). These algorithms are not consistent. Even the physical dimensionality of the equation is not assured. ‘Numerical’ problems in computer implementations of steepest descent algorithms can often be traced to the fact that the metric has been neglected.

Example 22. In the context of Example 20, where the misfit function $S(\mathbf{m})$ is given by

$$2S(\mathbf{m}) = (\mathbf{f}(\mathbf{m}) - \mathbf{d}_{\text{obs}})^t \mathbf{C}_D^{-1} (\mathbf{f}(\mathbf{m}) - \mathbf{d}_{\text{obs}}) + (\mathbf{m} - \mathbf{m}_{\text{prior}})^t \mathbf{C}_M^{-1} (\mathbf{m} - \mathbf{m}_{\text{prior}}), \quad (108)$$

the gradient $\hat{\mathbf{y}}$, whose components are $\hat{y}_\alpha = \partial S / \partial m^\alpha$, is given by the expression

$$\hat{\mathbf{y}}(\mathbf{m}) = \mathbf{F}^t(\mathbf{m}) \mathbf{C}_D^{-1} (\mathbf{f}(\mathbf{m}) - \mathbf{d}_{\text{obs}}) + \mathbf{C}_M^{-1} (\mathbf{m} - \mathbf{m}_{\text{prior}}), \quad (109)$$

where $\mathbf{F}$ is the matrix of partial derivatives

$$F^{i\alpha} = \frac{\partial f^i}{\partial m^\alpha}. \quad (110)$$

An example of computation of partial derivatives is given in Appendix M.

Example 23. In the context of Example 22 the model space $\mathcal{M}$ has an obvious metric, namely, that defined by the inverse of the ‘a priori’ covariance operator $\mathbf{g} = \mathbf{C}_M^{-1}$. Using this metric and the gradient given by Eq. (109), the steepest descent algorithm (107) becomes

$$\mathbf{m}_{k+1} = \mathbf{m}_k - \varepsilon_k (\mathbf{C}_M \mathbf{F}_k^t \mathbf{C}_D^{-1} (\mathbf{f}_k - \mathbf{d}_{\text{obs}}) + (\mathbf{m}_k - \mathbf{m}_{\text{prior}})), \quad (111)$$

where $\mathbf{F}_k \equiv \mathbf{F}(\mathbf{m}_k)$ and $\mathbf{f}_k \equiv \mathbf{f}(\mathbf{m}_k)$. The real positive quantities ε_k can be fixed after some trial and error by accurate linear search, or by using a linearized approximation.

Example 24. In the context of Example 22 the model space $\mathcal{M}$ has a less obvious metric, namely, that defined by the inverse of the ‘posterior’ covariance operator, $\mathbf{g} = \tilde{\mathbf{C}}_M^{-1}$.²³ Using this metric and the gradient given by Eq. (109), the steepest descent algorithm (107) becomes

$$\mathbf{m}_{k+1} = \mathbf{m}_k - \varepsilon_k (\mathbf{F}_k^t \mathbf{C}_D^{-1} \mathbf{F}_k + \mathbf{C}_M^{-1})^{-1} (\mathbf{F}_k^t \mathbf{C}_D^{-1} (\mathbf{f}_k - \mathbf{d}_{\text{obs}}) + \mathbf{C}_M^{-1} (\mathbf{m}_k - \mathbf{m}_{\text{prior}})), \quad (112)$$

where $\mathbf{F}_k \equiv \mathbf{F}(\mathbf{m}_k)$ and $\mathbf{f}_k \equiv \mathbf{f}(\mathbf{m}_k)$. The real positive quantities ε_k can be fixed, after some trial and error, by accurate linear search, or by using a linearized approximation that simply gives²⁴ $\varepsilon_k \approx 1$.

The algorithm (112) is usually called a ‘quasi-Newton algorithm.’ This name is not well chosen: a Newton method applied to minimization of a misfit function $S(\mathbf{m})$ would be a method using the second derivatives of $S(\mathbf{m})$, and thus the derivatives $H_{\alpha\beta}^i = \frac{\partial^2 f^i}{\partial m^\alpha \partial m^\beta}$, that are not computed (or not estimated) when using this algorithm. It is just a steepest descent algorithm with a nontrivial definition of the metric in the working space. In this sense it belongs to the wider class of ‘variable metric methods,’ not discussed in this article.

7.5 Estimating Posterior Uncertainties

In the Gaussian context, the Gaussian probability density that is tangent to $\sigma_m(\mathbf{m})$ has its center at the point given by the iterative algorithm

$$\mathbf{m}_{k+1} = \mathbf{m}_k - \varepsilon_k (\mathbf{C}_M \mathbf{F}_k^t \mathbf{C}_D^{-1} (\mathbf{f}_k - \mathbf{d}_{\text{obs}}) + (\mathbf{m}_k - \mathbf{m}_{\text{prior}})), \quad (113)$$

(Eq. (111)) or, equivalently, by the iterative algorithm

$$\mathbf{m}_{k+1} = \mathbf{m}_k - \varepsilon_k (\mathbf{F}_k^t \mathbf{C}_D^{-1} \mathbf{F}_k + \mathbf{C}_M^{-1})^{-1} (\mathbf{F}_k^t \mathbf{C}_D^{-1} (\mathbf{f}_k - \mathbf{d}_{\text{obs}}) + \mathbf{C}_M^{-1} (\mathbf{m}_k - \mathbf{m}_{\text{prior}})) \quad (114)$$

(Eq. (112)). The covariance of the tangent Gaussian is

$$\tilde{\mathbf{C}}_M \approx (\mathbf{F}_\infty^t \mathbf{C}_D^{-1} \mathbf{F}_\infty + \mathbf{C}_M^{-1})^{-1}, \quad (115)$$

where $\mathbf{F}_\infty$ refers to the value of the matrix of partial derivatives at the convergence point.

7.6 Some Comments on the Use of Deterministic Methods

7.6.1 Linear, Weakly Nonlinear and Nonlinear Problems

There are different degrees of nonlinearity. Figure 8 illustrates four domains of nonlinearity, calling for different

FIGURE 8 A simple example where we are interested in predicting the gravitational field $\mathbf{g}$ generated by a 2D distribution of mass.

FIGURE 9 Illustration of the four domains of nonlinearity, calling for different optimization algorithms. The model space is symbolically represented by the abscissa, and the data space is represented by the ordinate. The gray oval represents the combination of prior information on the model parameters and information from the observed data. What is important is not an intrinsic nonlinearity of the function relating model parameters to data, but how linear the function is *inside the domain of significant probability*.

optimization algorithms. In this figure the abscissa symbolically represents the model space, and the ordinate represents the data space. The gray oval represents the combination of prior information on the model parameters, and information from the observed data.²⁵ It is the probability density $\rho(\mathbf{d}, \mathbf{m}) = \rho_d(\mathbf{d})\rho_m(\mathbf{m})$ seen elsewhere.

To fix ideas, the oval suggests here a Gaussian probability, but our distinction between problems according to their nonlinearity will not depend fundamentally on this.

First, there are strictly linear problems. For instance, in the example illustrated by Figure 8 the gravitational field $\mathbf{g}$ depends linearly on the masses inside the blocks.²⁶

Strictly linear problems are illustrated at the top left of Figure 9. The linear relationship between data and model parameters, $\mathbf{d} = \mathbf{G}\mathbf{m}$, is represented by a straight line. The prior probability density $\rho(\mathbf{d}, \mathbf{m})$ ‘induces’ on this straight line the posterior probability density²⁷ $\sigma(\mathbf{d}, \mathbf{m})$ whose ‘projection’ over the model space gives the posterior probability density over the model parameter space, $\sigma_m(\mathbf{m})$. Should the prior probability densities be Gaussian, then the posterior probability distribution would also be Gaussian: this is the simplest situation.

Quasi-linear problems are illustrated at the bottom left of Figure 9. If the relationship linking the observable data $\mathbf{d}$ to the model parameters $\mathbf{m}$,

$$\mathbf{d} = \mathbf{g}(\mathbf{m}), \quad (116)$$

is approximately linear *inside the domain of significant prior probability* (i.e., inside the gray oval of the figure), then the posterior distribution is just as simple as the prior distribution. For instance, if the prior is Gaussian the posterior is also Gaussian.

In this case also, the problem can be reduced to the computation of the mean and the covariance of the Gaussian. Typically, one begins at some ‘starting model’ $\mathbf{m}_0$ (typically, one takes for $\mathbf{m}_0$ the ‘a priori model’ $\mathbf{m}_{\text{prior}}$),²⁸ linearizing the function $\mathbf{d} = \mathbf{g}(\mathbf{m})$ around $\mathbf{m}_0$, and one looks for a model $\mathbf{m}_1$ ‘better than $\mathbf{m}_0$.’

Iterating such an algorithm, one tends to the model $\mathbf{m}_\infty$ at which the ‘quasi-Gaussian’ $\sigma_m(\mathbf{m})$ is maximum. The linearizations made in order to arrive to $\mathbf{m}_\infty$ are so far not an approximation: the point $\mathbf{m}_\infty$ is perfectly defined, independently of any linearization and any method used to find it. But once the convergence to this point has been obtained, a linearization of the function $\mathbf{d} = \mathbf{g}(\mathbf{m})$ around this point,

$$\mathbf{d} - \mathbf{g}(\mathbf{m}_\infty) = \mathbf{G}_\infty(\mathbf{m} - \mathbf{m}_\infty), \quad (117)$$

allows to obtain a good approximation to the posterior uncertainties. For instance, if the prior distribution is Gaussian this will give the covariance of the ‘tangent Gaussian.’

Between linear and quasi-linear problems there are the ‘linearizable problems.’ The scheme at the top right of

Figure 9 shows the case where the linearization of the function $\mathbf{d} = \mathbf{g}(\mathbf{m})$ around the prior model,

$$\mathbf{d} - \mathbf{g}(\mathbf{m}_{\text{prior}}) = \mathbf{G}_{\text{prior}}(\mathbf{m} - \mathbf{m}_{\text{prior}}), \quad (118)$$

gives a function that, inside the domain of significant probability, is very similar to the true (nonlinear) function.

In this case, there is no practical difference between this problem and the strictly linear problem, and the iterative procedure necessary for quasi-linear problems is here superfluous.

It remains to analyze the true nonlinear problems that, using a pleonasm, are sometimes called *strongly nonlinear problems*. They are illustrated at the bottom right of Figure 9.

In this case, even if the prior distribution is simple, the posterior distribution can be quite complicated. For instance, it can be multimodal. These problems are in general quite complex to solve, and only a Monte Carlo analysis, as described in the previous chapter, is feasible.

If full Monte Carlo methods cannot be used, because they are too expensive, then one can mix a random part (for instance, to choose the starting point) and a deterministic part. The optimization methods applicable to quasi-linear problems can, for instance, allow us to go from the randomly chosen starting point to the ‘nearest’ optimal point. Repeating these computations for different starting points, one can arrive at a good idea of the posterior distribution in the model space.

7.6.2 The Maximum Likelihood Model

The *most likely model* is, by definition, that at which the volumetric probability (see Appendix A) $\sigma_\beta(\mathbf{m})$ attains its maximum. As $\sigma_\beta(\mathbf{m})$ is maximum when $S(\mathbf{m})$ is minimum, we see that the most likely model is also the ‘best model’ obtained when using a ‘least-squares criterion.’ Should we have used the double exponential model for all the

FIGURE 10 One of the circumstances where the ‘maximum likelihood model’ may not be very interesting is when it corresponds to a narrow maximum with small total probability, as the peak in the left part of this probability distribution.

FIGURE 11 At the top right and bottom left and right, three random realizations of a Gaussian random function with zero mean and (approximately) exponential correlation function. The most likely function, i.e., the center of the Gaussian, is shown at the top left. We see that the most likely function is not a representative of the probability distribution.

uncertainties, then the most likely model would be defined by a ‘least absolute values’ criterion.

There are many circumstances where the most likely model is not an interesting model. One trivial example is when the volumetric probability has a ‘narrow maximum,’ with small total probability (see Fig. 10). A much less trivial situation arises when the number of parameters is very large, as for instance when we deal with a random function (that, strictly speaking, corresponds to an infinite number of random variables). Figure 11, for instance, shows a few realizations of a Gaussian function with zero mean and an (approximately) exponential correlation. The most likely function is the center of the Gaussian, i.e., the null function shown at the top left. But this is not a representative sample of the probability distribution, as any realization of the probability distribution will have, with a probability very close to one, the ‘oscillating’ characteristics of the other three samples.

8. Conclusions

Probability theory is well adapted to the formulation of inverse problems, although its formulation must be rendered intrinsic (introducing explicitly the definition of distances in the working spaces, by redefining the notion of conditional probability density, and by introducing the notion of conjunction of states of information). The Metropolis algorithm is well adapted to the solution of inverse problems, as its inherent structure allows us to sequentially combine prior

information, theoretical information, etc., and allows us to take advantage of the ‘movie philosophy.’ When a general Monte Carlo approach cannot be afforded, one can use simplified optimization techniques (like least squares). However, this usually requires strong simplifications that can only be made at the cost of realism.

Acknowledgements

We are very indebted to our colleagues (Bartolomé Coll, Miguel Bosch, Guillaume Évrard, John Scales, Christophe Barnes, Frédéric Parrenin, and Bernard Valette) for illuminating discussions. We are also grateful to the students of the Geophysical Tomography Group, and the students at our respective institutes (in Paris and Copenhagen).

Notes

- For instance, we could fit our observations with a heterogeneous but isotropic Earth model or, alternatively, with a homogeneous but anisotropic Earth.
- Preliminary Earth Reference Model (PREM), Dziewonski and Anderson, PEPI, 1981. Inversion for Centroid Moment Tensor (CMT), Dziewonski, Chou and Woodhouse, JGR, 1982. First global tomographic model, Dziewonski, JGR, 1984.
- The capacity element associated to the vector elements $d\mathbf{r}_1, d\mathbf{r}_2, \dots, d\mathbf{r}_n$ is defined as $d\tau = \varepsilon_{ij\dots k} dr_1^i dr_2^j \dots dr_n^k$, where $\varepsilon_{ij\dots k}$ is the Levi-Civita capacity (whose components take the values $\{0, \pm 1\}$). If the metric tensor of the space is $\mathbf{g}(\mathbf{x})$, then $\eta_{ij\dots k} = \sqrt{\det \mathbf{g}} \varepsilon_{ij\dots k}$ is a true tensor, as it is the product of a density $\sqrt{\det \mathbf{g}}$ by a capacity $\varepsilon_{ij\dots k}$. Then, the volume element, defined as $dV = \eta_{ij\dots k} dr_1^i dr_2^j \dots dr_n^k = \sqrt{\det \mathbf{g}} d\tau$, is a (true) scalar.
- This is a property that is valid for any coordinate system that can be chosen over the space.
- As a counterexample, the distance defined as $ds = |dx| + |dy|$ is not of the L_2 type (it is L_1).
- This solves the complete problem for isotropic tensors only. It is beyond the scope of this text to propose rules valid for general anisotropic tensors: the necessary mathematics have not yet been developed.
- The definition of the elastic constants was made before the tensorial structure of the theory was understood. Seismologists today should not use, at a theoretical level, parameters like the first Lamé coefficient λ or the Poisson ratio. Instead they should use κ and μ (and their inverses). In fact, our suggestion in this IASPEI volume is to use the true eigenvalues of the stiffness tensor, $\lambda_\kappa = 3\kappa$, and $\lambda_\mu = 2\mu$, which we propose to call the *eigen-bulk-modulus* and the *eigen-shear-modulus*, respectively.
- Assume that $p(\mathbf{x})$ and $q(\mathbf{x})$ are normalized by $\int_{\mathcal{X}} d\mathbf{x} p(\mathbf{x}) = \mathbf{1}$ and $\int_{\mathcal{X}} d\mathbf{x} q(\mathbf{x}) = \mathbf{1}$. Then, irrespective of the normalizability of $\mu(\mathbf{x})$ (as explained above, $p(\mathbf{x})$ and $q(\mathbf{x})$ are assumed to be absolutely continuous with respect to the homogeneous distribution), $(p \wedge q)(\mathbf{x})$ is normalizable, and its normalized expression is
$$(p \wedge q)(\mathbf{x}) = \frac{p(\mathbf{x}) q(\mathbf{x}) / \mu(\mathbf{x})}{\int_{\mathcal{X}} d\mathbf{x} p(\mathbf{x}) q(\mathbf{x}) / \mu(\mathbf{x})}.$$
- As a counter example, working at the surface of the sphere with geographical coordinates $(\mathbf{u}, \mathbf{v}) = (u, v) = (\vartheta, \varphi)$ this condition is **not** fulfilled, as $g_\varphi = \sin \theta$ is a function of ϑ : the surface of the sphere is not the Cartesian product of two 1D spaces.
- That is, series of numbers that appear random if tested with any reasonable statistical test.
- To see this, put $f(\mathbf{x}) = \mathbf{1}$, $\mu(\mathbf{x}) = \mathbf{1}$, and $g(\mathbf{x}) = \frac{\exp(-E(\mathbf{x})/T)}{\int \exp(-E(\mathbf{x})/T) d\mathbf{x}}$, where $E(\mathbf{x})$ is an ‘energy’ associated to the point $\mathbf{x}$, and T is a ‘temperature’. The summation in the denominator is over the entire space. In this way, our acceptance rule becomes the classical Metropolis rule: point $\mathbf{x}_i$ is always accepted if $E(\mathbf{x}_i) \leq E(\mathbf{x}_j)$, but if $E(\mathbf{x}_i) > E(\mathbf{x}_j)$, it is only accepted with probability $p_{ij}^{\text{acc}} = \exp(-(E(\mathbf{x}_i) - E(\mathbf{x}_j))/T)$.
- A numerical method is called robust if it is not sensitive to a small number of large errors.
- It would be violated, for instance, if we use the pair of elastic parameters longitudinal wave velocity – shear wave velocity, as the volume element in the space of elastic wave velocities does not factorize (see Appendix H).
- We use here the properties $\log \sqrt{\mathbf{A}} = \frac{1}{2} \log \mathbf{A}$, and $\det \mathbf{A} \mathbf{B} = \det \mathbf{B} \mathbf{A}$.
- Typically, this may happen because the derivatives $\mathbf{F}$ are small or because the variances in $\mathbf{C}_M$ are large.
- We first use $\log \det \mathbf{A} = \text{trace} \log \mathbf{A}$, and then the series expansion of the logarithm of an operator, $\log(\mathbf{I} + \mathbf{A}) = \mathbf{A} - \frac{1}{2} \mathbf{A}^2 + \dots$.
- Practically, it may correspond to the output of some ‘black box’ solving the ‘forward problem’.
- Remember that, even if we wish to use a simple method based on the notion of conditional probability density, an analytic expression like $\mathbf{d} = \mathbf{f}(\mathbf{m})$ needs some ‘thickness’ before going to the limit defining the conditional probability density. This limit crucially depends on the ‘thickness’, i.e., on the type of uncertainties the theory contains.
- Note that taking the limit of $\vartheta(x, t)$ or of $\rho(x, t)$ for infinite variances we obtain $\mu(x, t)$, as we should.
- The ratio $F(\mathbf{x}) = f(\mathbf{x}) v(\mathbf{x})$ is what we refer to as the *volumetric probability* associated to the probability density $f(\mathbf{x})$. See Appendix A.
- We take this example because typical misfit functions are adimensional (have no physical dimensions) but the argument has general validity.

22. As shown in Tarantola (1987), if γ_k is the direction of steepest ascent at point $\mathbf{m}_k$, i.e., $\gamma_k = \mathbf{C}_M \mathbf{F}_k^t \mathbf{C}_D^{-1} (\mathbf{f}_k - \mathbf{d}_{\text{obs}}) + (\mathbf{m}_k - \mathbf{m}_{\text{prior}})$, then, a local linearized approximation for the optimal ε_k gives

$$\varepsilon_k = \frac{\gamma_k^t \mathbf{C}_M^{-1} \gamma_k}{\gamma_k^t (\mathbf{F}_k^t \mathbf{C}_D^{-1} \mathbf{F}_k + \mathbf{C}_M^{-1}) \gamma_k}.$$

23. The ‘best estimator’ of $\tilde{\mathbf{C}}_M$ is

$$\tilde{\mathbf{C}}_M \approx (\mathbf{F}_k^t \mathbf{C}_D^{-1} \mathbf{F}_k + \mathbf{C}_M^{-1})^{-1}. \quad (119)$$

See, e.g., Tarantola (1987).

24. While a sensible estimation of the optimal values of the real positive quantities ε_k is crucial for the algorithm 111, they can in many usual circumstances be dropped from the algorithm 113.
25. The gray oval is the product of the probability density over the model space, representing the prior information, and the probability density over the data space representing the experimental results.
26. The gravitational field at point $\mathbf{x}_0$ generated by a distribution of volumetric mass $\rho(\mathbf{x})$ is given by

$$\mathbf{g}(\mathbf{x}_0) = \int dV(\mathbf{y}) \frac{\mathbf{x}_0 - \mathbf{y}}{\|\mathbf{x}_0 - \mathbf{y}\|^3} \rho(\mathbf{x}).$$

When the volumetric mass is constant inside some predefined (2D) volumes, as suggested in Figure 8, this gives

$$\mathbf{g}(\mathbf{x}_0) = \sum_A \sum_B \mathbf{G}^{A,B}(\mathbf{x}_0) m^{A,B}.$$

This is a strictly linear equation between data (the gravitational field at a given observation point) and the model parameters (the masses inside the volumes). Note that if instead of choosing as model parameters the total masses inside some predefined volumes one chooses the geometrical parameters defining the sizes of the volumes, then the gravity field is not a linear function of the parameters. More details can be found in Tarantola and Valette (1982b, page 229).

27. Using the ‘orthogonal-limit’ method described in Section 2.4.
28. The term ‘a priori model’ is an abuse of language. The correct term is ‘mean a priori model’.

Editor’s Note

Appendixes A–P are placed on the attached Handbook CD, under the directory \16Mosegaard. An introduction to probability concepts is given in Chapter 82, Statistical Principles for Seismologists, by Vere-Jones and Ogata. Challenges in Observational Seismology

W.H.K. Lee

US Geological Survey, Menlo Park, California, USA (retired)

1. Introduction

Earthquake seismology became a quantitative scientific discipline after instruments were developed to record seismic waves in the late 19th century (Dewey and Byerly, 1969; Chapter 1 by Agnew). Earthquake seismology is essentially based on *field* observations. The great progress made in the past several decades was primarily due to increasingly plentiful and high-quality data that are readily distributed. Our ability to collect, process, and analyze earthquake data has been accelerated by advances in electronics, communications, computers, and software (see Chapter 85 edited by Snoke and Garcia-Fernandez).

Instrumental observation of earthquakes has been carried out for a little over 100 years by seismic stations and networks of various sizes, from local to global scales (see Chapter 87 edited by Lahr and van Eck). The observed data have been used, for example, (1) to compute the source parameters of earthquakes, (2) to determine the physical properties of the Earth's interior, (3) to test the theory of plate tectonics, (4) to map active faults, (5) to infer the nature of damaging ground shaking, and (6) to carry out seismic hazard analysis. Construction of a satisfactory theory of the earthquake process has not yet been achieved within the context of physical laws. Good progress, however, has been made in building a physical foundation of the earthquake source process, partly as a result of research directed toward earthquake prediction.

This chapter is intended for a general audience. Technical details are not given, but relevant references and chapters in this Handbook are referred to. The first part of this chapter presents a brief overview of the observational aspects of earthquake seismology, concentrating on instrumental observations of seismic waves generated by earthquakes (i.e., seismic monitoring), and readers are referred to Chapter 49 by Musson and Cecic for noninstrumental observations. A few key developments and practices are summarized by taking a general view, since many national and regional developments

have been chronicled in national and institutional reports (see Chapter 79 edited by Kisslinger). In the latter part of this chapter, the nature of seismic monitoring and some challenges in observational seismology are discussed from a *personal* perspective. Comments of a technical or *philosophical* nature are given in the Notes at the end of the chapter, and they are referenced by superscript numbers in the text.

2. Some Basic Information about Seismographs and Earthquakes

Besides geodetic data (see, e.g., Chapter 37 by Feigl), the primary instrumental data for the quantitative study of earthquakes are *seismograms*, records of ground motion caused by the passage of seismic waves generated by earthquakes. Seismograms are written by *seismographs*, instruments that detect and record ground motion with timing information. A seismograph usually consists of three components: (1) a seismometer that responds to ground motion and produces a signal proportional to acceleration, velocity, or displacement over a range of input motions in amplitude and in frequency; (2) a timing device; and (3) a recording device that writes seismograms (ground motion plus time marks) on papers or on electronic storage media. An *accelerograph* is a seismograph designed to record the time history of acceleration of strong ground motion on scale. Most modern seismographs are *velocigraphs* recording the time history of ground velocity. See Chapter 18 by Wielandt for a discussion of seismometry. A seismic network (or array) is a group of seismographs that are "linked" to a central headquarters. The link is by various methods of telemetry nowadays, and was by mail or telegraphy in the early days, or simply by manual collecting of the records. When we speak of a seismic *station*, it may be an observatory with multiple instruments in special vaults, or a small instrument package buried in a remote unmanned site.

In 1935 C.F. Richter introduced the concept of *magnitude* to classify local earthquakes by their “size.” See Chapter 44 by Utsu for a discussion of the various magnitude scales in use. Existing instruments and environments are such that the smallest natural earthquakes we routinely observe are about magnitude 0. The largest earthquake so far for which we have instrumental records is the magnitude 9.5 Chilean earthquake in 1960. Some commonly accepted adjectives used to describe the approximate size or magnitude (M) of an earthquake are “major” for $M \geq 7$ (“great” if $M \geq 8$), “moderate” for $5 \leq M < 7$, “small” for $3 \leq M < 5$, and “micro” for $M < 3$.

In 1941, B. Gutenberg and C.F. Richter discovered that over large geographic regions the frequency of earthquake occurrence is empirically related to magnitude by $\log N = a - bM$, where N is the number of earthquakes of magnitude M or greater, and a and b are numerical constants. Usually $b \approx 1$, implying, for example, that $M=6$ earthquakes are about 10 times more frequent than $M=7$ earthquakes. See Chapter 43 by Utsu for further detail. Engdahl and Villaseñor in Chapter 41 show that there has been an *average* of about 15 major (i.e., $M \geq 7$) earthquakes per year over the past 100 y. A list of deadly earthquakes of the world for the past five centuries has been compiled by Utsu in Chapter 42. It shows that $M \geq 6$ earthquakes (about 150 in the world per year) can be damaging and deadly if they occur in populated areas and if their focal depths are shallow (e.g., < 50 km). Strong ground motions above 0.1g in acceleration are mainly generated by $M \geq 6$ earthquakes.

3. Seismic Networks for Observing Earthquakes

Seismic waves from earthquakes have a vast range in amplitude and frequency (see Fig. 1 of Hutt *et al.* in Chapter 20—about 10 orders in amplitude of ground acceleration, from 10^{-7} to 10^3 cm sec^{-2} , and about 7 orders in frequency, from 10^{-5} to 10^2 Hz). Since no single instrument type can cover such vast ranges, seismographs and seismic networks have evolved from three different *optimizing* choices, as discussed in the next three subsections. National reports, including those from Germany, Japan, Russia, the United Kingdom, and the United States (collected in Chapter 79, edited by Kisslinger), contain detailed early history on a national basis. For example, Kisslinger and Howell give a detailed account of historical developments in the United States to about 1960 in the USA National Report.

3.1 Seismic Networks Optimized for Teleseisms

Teleseisms are *distant* earthquakes that are big enough to produce measurable seismic waves at great distances. A major earthquake occurs about once a month (or a potentially

damaging earthquake occurs about *every week*) somewhere in the world (but rarely in one’s own backyard), and is recorded on the seismograms of seismographs optimized for teleseisms. These seismograms also draw interest from research seismologists worldwide, as teleseisms are excellent sources of seismic waves for probing the Earth’s interior (see, e.g., Chapter 11 by Romanowicz; Chapter 52 by Curtis and Snieder).

3.1.1 Early Years

In the beginning of instrumental seismology, observatories with various types of seismographs operated independently. The observatories were linked by mail, which could take months. Many seismological studies require seismograms or their readings from multiple stations. For example, arrival times of seismic waves from at least four well-distributed stations are needed to locate an earthquake satisfactorily. Even after one managed to get a few seismograms, it was difficult to work with records from different instruments with poorly synchronized time.

In the late 19th century the need for *standardization* and for *data exchange* was recognized by G. Gerland, J. Milne, and E. Rebeur-Paschwitz. With the support of the British Association for the Advancement of Science, over 30 Milne seismographs were placed at locations throughout the British Empire beginning in the late 1890s, and seismogram readings were reported to Milne’s observatory at Shide on the Isle of Wight (see the UK National Report in Chapter 79). A global earthquake summary with seismogram readings was issued by John Milne beginning in 1899. These summaries are now known as the “Shide Circulars” (see Chapter 88 by Schweitzer and Lee). Milne seismographs were soon superseded by more advanced instruments,¹ and the headquarters of the International Association of Seismology was established in Strasbourg (see the German National Report in Chapter 79).

Seismographs for recording teleseisms were established at many observatories, especially meteorological and astronomical observatories. The early enthusiasts were academic professors, Jesuits, and gentleman scientists. See Chapter 89 edited by Howell for biographies of some notable pioneers. Revolutions and wars, however, frequently disrupted progress, especially in collecting and distributing earthquake information, during the first half of the 20th century.²

3.1.2 WWSSN and ESSN

In the late 1950s, attempts to negotiate a comprehensive test ban treaty failed, in part because of perceptions that seismic methods were inadequate for monitoring the underground environment for nuclear testing (see Chapter 24 by Richards). The influential Berkner report of 1959 advocated major support for seismology (see article by Kisslinger and Howell in the USA National Report in Chapter 79). As a result, the World Wide Standardized Seismograph Network (WWSSN) was created with about 120 continuously recording stations, located over much of the world (except China and USSR) in the early

1960s (Oliver and Murphy, 1971). Each WWSSN station was equipped with *identical* sets of short-period and long-period three-component seismographs and *accurate* chronometers. Seismograms were sent to the United States to be photographed onto 70-mm film chips for distribution (about \$1 per chip). This network is credited with making possible rapid progress in global seismology, and with aiding the plate tectonic revolution in the Earth sciences in the late 1960s (see, e.g., Chapter 6 by Uyeda; article by Sykes in the USA National Report in Chapter 79).

At about the same time, the Unified System of Seismic Observations (ESSN) of the former USSR and its allied countries was established, consisting of almost 100 stations equipped with Kirnos short-period, broadband (1–20 sec displacement sensing) and long-period seismographs. See the Russian National Report in Chapter 79 for details.

Despite its great success, the WWSSN declined starting in the mid-1970s. By then it had produced 3 million analog seismograms, far more than seismologists could process and analyze. After about ten years of operation, funding for the WWSSN began to disappear. Although the initial costs were funded by the US Defense Advanced Research Projects Agency (DARPA), their emphasis is in research and not in long-term operation. Funding for continuing the WWSSN was then left to the National Oceanic and Atmospheric Administration (NOAA) and then to the US Geological Survey (USGS). Because of statutory restriction, USGS could not support global stations outside the United States. Although the US National Science Foundation (NSF) did pick up the funding for supporting foreign stations for some time, NSF also wanted to avoid funding any ongoing seismic networks. In addition, the emphasis in seismology was shifting to earthquake prediction at the USGS, then considered a new and promising venture.³ Earthquake prediction, however, turned out to be far more difficult than anticipated, as reviewed for example, by Kanamori in Chapter 72.

3.1.3 The Digital Revolution and the GDSN

Since *analog* seismograms have a low dynamic range (about 3 orders or less in amplitude) and must be digitized before computer processing, some seismologists recognized that “digital” instrumentation should be developed to achieve a much higher dynamic range and for ease of computer processing. Many scientists and engineers in other disciplines had already been making great advances in that direction because of the emerging digital technology in the 1970s. Seismologists also recognized that the tandem use of short-period and long-period instruments was needed to avoid the natural seismic noise (see Chapter 19 by Webb). They realized that a new global seismic network should be rebuilt with (1) broadband, high dynamic range seismographs, (2) digital electronics, (3) communication by telemetry or a mass storage medium, and (4) processing by computers in mind.

According to Duncan Agnew (personal communication, 2001), the idea of digital recording goes back to 1960, but it was not practical until the late 1970s, and Block and Moore (1966) pioneered the use of the feedback gravimeter. The introduction of electronic force feedback to sealed inertial seismometers (Melton, 1976; Wielandt and Streckeisen, 1982) together with the application of high-resolution analog-to-digital converters made it possible to construct very broadband, large dynamic range seismograph systems. The first major digital broadband installation was the German Gräfenberg (GRF) array, the first station of which started recording in 1975 (Harjes and Seidl, 1978).

The International Deployment of Accelerometers (IDA) Project was created in the 1970s as a global *digital* seismic network to collect data for low-frequency seismology (Agnew *et al.*, 1976). Among the many contributions made by IDA are much improved studies of the Earth’s free oscillation, long-period source mechanics for major earthquakes, and the aspherical structure of the Earth’s interior (see Chapter 51 by Lay). Another notable effort in global digital seismic networks was the French GEOSCOPE Program (Romanowicz *et al.*, 1991), and the German GEOFON project.

With the availability of broadband, large dynamic range, force feedback seismometers and 24-bit digitizers, many of the WWSSN stations were replaced by broadband digital systems starting in the 1980s (see Chapter 20 by Hutt *et al.*). A global digital seismic network has emerged since the 1980s under the guidance of two effective organizations (the International Federation of Digital Broadband Seismographic Networks, FDSN, and the Incorporated Research Institutions for Seismology, IRIS).⁴ Digital seismograms recorded by stations worldwide are now readily available via the Internet from the IRIS Data Management Center within tens of minutes of an $M \approx 6$ or larger earthquake occurring anywhere in the world (see Chapter 86 by Aherne), as well as through the European ORFEUS center at de Bilt, The Netherlands, the GEOFON center at the GeoForschungsZentrum, Potsdam, Germany, and several other centers.

3.2 Seismic Networks Optimized for Regional Earthquakes

Another major development in seismic monitoring was the establishment of seismic networks optimized to record the *more frequent* but *smaller* regional and local earthquakes. In order to observe as many nearby earthquakes as possible, seismographs with high magnifications are adopted to record as small an earthquake as the technology and background noise allow. A consequence of this requirement, when applied to inexpensive sensors and telemetry with low dynamic range, is that the recorded amplitudes are saturated for earthquakes with $M > \sim 3$ within about 50 km. This is not a serious defect, because the emphasis is to obtain as many first-arrival times as possible, so that more earthquakes can be detected and located. Since

seismic waves from small earthquakes are quickly attenuated with distance, it is also necessary to deploy many instruments with small station spacing (several to a few tens of kilometers), and to cover as large a territory as possible in order to record at least a few earthquakes every week. Since funding is finite, the regional seismic networks are usually optimized for a large number of stations rather than for high data quality.

3.2.1 A Brief History

In the 1910s, the Carnegie Institution of Washington (CIW)⁵ was spending large sums of money building the world's largest telescope in southern California. Since astronomers were concerned about earthquakes that might disturb their telescopes, H.O. Wood was able to persuade CIW to support earthquake investigations. As a result, a regional network of about a dozen Wood–Anderson seismographs was established in southern California in the 1920s. See Goodstein (1991) for the early history leading to the establishment of the California Institute of Technology (Caltech) and its Seismological Laboratory. Many astronomers played important roles in getting seismic monitoring established in various regions of the world.

Regional networks using different seismographs were also established in many countries, such as Japan, New Zealand, and the USSR with its allies. In the 1960s, high-gain, short-period, telemetered networks were developed to study microearthquakes (see, e.g., Eaton, 1989). Over 100 microearthquake networks were implemented by the 1970s in various parts of the world for detailed studies of local earthquakes and especially for the purpose of earthquake prediction (Lee and Stewart, 1981). These microearthquake networks consisted of tens to hundreds of short-period seismometers with their signals telemetered into central recording sites for processing and analysis. High magnification was achieved by electronic amplification, which permitted recording of very small earthquakes (down to magnitude 0) at the expense that the recorded seismic wave amplitudes were saturated for earthquakes of $M > \sim 3$. Some microearthquake networks soon expanded into regional seismic networks.

As with the WWSSN, it was difficult to improve and sustain regional seismic networks for long in many countries. For example, by the 1980s the regional seismic networks in the United States were in decline. The 1989 Loma Prieta earthquake and the 1994 Northridge earthquake demonstrated that the existing regional seismic networks in the United States were not satisfactory, especially during large damaging earthquakes.⁶ With new funding in response to these disastrous earthquakes, a new life began in the form of real-time seismology.

3.2.2 Some Recent Advances

Because of recent advances in electronics, communications, and microcomputers, it is now possible to deploy sophisticated digital seismograph stations at global, national, and local scales

for *real-time* seismology (Kanamori *et al.*, 1997). Many such networks, including portable networks, have been implemented in many countries. In particular, various real-time and near real-time seismic systems began operation in the 1990s. For example, Mexico (Chapter 76 by Espinosa-Aranda), California (Chapter 77 by Gee *et al.*; Chapter 78 by Hauksson *et al.*), and Taiwan (Teng *et al.*, 1997).

For example, the Real-time Data (RTD) system operated by the Seismological Observation Center of the Central Weather Bureau in Taiwan is based on a network of telemetered digital accelerographs (see Chapter 64 by Shin *et al.*). This system, using pagers, e-mail and other techniques, has automatically and rapidly issued information on the hypocenter, magnitude, and shaking amplitude of felt earthquakes ($M > \sim 4$) in the Taiwan region since 1995. The disastrous Chi-Chi earthquake ($M_W = 7.6$) of 20 September 1999 caused 2471 deaths and an estimated economic losses of US \$14 billion. For this earthquake sequence, the RTD system delivered accurate information (102 sec after the main shock and about 50 sec for most aftershocks) to officials and proved to be useful for emergency response by the Taiwan government (Wu *et al.*, 2000; Goltz *et al.*, 2001).

3.3 Seismic Networks Optimized to Record Damaging Ground Shaking

Observing teleseisms at a spacing of several hundreds of kilometers does not yield the information about near-source strong ground shaking required for earthquake engineering purposes. A few hundred global stations, therefore, cannot provide the detailed data necessary to help in reducing seismic hazards. Broadband seismometers optimized to record earthquakes at great distances are not designed to perform well in the near field of a major earthquake. For example, during the 1999 Chi-Chi earthquake the *nearest* broadband station in Taiwan (epicentral distance of about 20 km) recorded mostly saturated amplitude data and stopped about one minute into the shock (see Kao and Angelier, 2001, for the recorded seismogram).

A regional seismic network with spacing of a few tens of kilometers cannot do the job either. The station spacing is still too large and, worse yet, the records are often saturated for earthquakes with magnitude $> \sim 3$, including a *big one* if it should occur. In his account of the early history of earthquake engineering, Housner in Chapter 2 credited John R. Freeman, an eminent engineer, for persuading the then US Secretary of Commerce to authorize a strong-motion program and in particular the design of an accelerograph for engineering purposes in 1930. In a letter to R.R. Martel (Housner's professor) at Caltech, Freeman wrote:

I stated that the data which had been given to structural engineers on acceleration and limits of motion in earthquakes as a basis for their designs were all based on guesswork, that there had never yet been a precise

measurement of acceleration made. That of the five seismographs around San Francisco Bay which tried to record the Earthquake of 1906 not one was able to tell the truth.

Strong-motion recordings useful for engineering purposes are on-scale recordings of damaging earthquakes; in particular, recordings on or near structures in densely urbanized environments, within 20 km of the earthquake-rupture zone for sites on rock and within about 100 km for sites on soft soils. Recordings of motions at levels sufficient to cause damage at sites at greater distances also are of interest for earthquake engineering in areas likely to be affected by major subduction zone earthquakes or in areas with exceptionally low attenuation rates (Borcherdt, 1997).

Although several interesting accelerograms were recorded in southern California in the 1930s and 1940s, to the delight of earthquake engineers, most seismologists did not pursue strong-motion monitoring until much later. The 1971 San Fernando earthquake demonstrated the need for strong-motion data for engineering purposes (see Chapter 57 by Anderson). Two important programs merged in the United States—the National Strong-Motion Program (<http://nsmg.wr.usgs.gov/>), and the California Strong Motion Instrumentation Program (<http://docinet3.consrv.ca.gov/csmip/>). However, their budgets were and continue to be small in comparison with those of other earthquake programs. High levels of funding for strong-motion monitoring (comparable to that of the GDSN and the regional seismic networks) occurred in Taiwan and Japan in the early and mid-1990s, respectively (see Section 5.1). The Consortium of Organizations for Strong-Motion Observation Systems (<http://www.cosmos-eq.org/>) has recently been established to promote the acquisition and application of strong-motion data.

4. Record Keeping and Data Processing on a Global Scale

Many scientific advances are based on accurate and long-term observations. Because disastrous earthquakes in a given region recur on a time scale of tens to hundreds of years, special efforts are needed to ensure that seismic monitoring is carried out in a consistent manner in keeping records, detecting and timing all locatable events, and processing the observed and derived data. The amount of data in earthquake seismology is large and growing⁷ and may be classified into six types (with their approximate annual output rate) as follows:

1. Information for instrument location, characteristics, and operational details: 2×10^7 bytes y^{-1} .
2. Raw observational data (continuous signals from seismographs): 10^{14} bytes y^{-1} .
3. Earthquake waveform data (containing seismic events): 5×10^{12} bytes y^{-1} .

4. Earthquake phase data, such as P , S , and secondary arrival times, maximum amplitude and period, first motion direction, signal duration, etc.: 5×10^8 bytes y^{-1} .
5. Event lists of origin time, epicenter coordinates, focal depth, magnitude, etc.: 2×10^7 bytes y^{-1} .
6. Scientific reports describing seismicity, focal mechanisms, etc.: 5×10^7 bytes y^{-1} .

Seismic monitoring for the entire world depends on continuous international cooperation as discussed in Chapter 4 by Adams, because seismic waves propagate throughout the Earth without regard to national boundaries. Seismologists need not only to exchange scientific results (via reports and papers published in journals or books), but also to rely on the exchange of primary data (i.e., seismograms) and their derived products (e.g., phase data). Each seismic observatory can interpret its recorded seismograms, but single-station data are insufficient for the study of earthquakes, especially those occurring some distance away.

The International Seismological Centre (ISC) is charged with the final collection, analysis, and publication of standard earthquake information from all over the world (Willemann and Storchak, 2001). The ISC bulletins (issued since 1964) are the definitive summary of reported earthquake phase data, and from these data the earthquake parameters are determined by a standard procedure. These bulletins are published with a time lag of about two years in order to incorporate as much information as possible from cooperating seismic stations. Engdahl and Villaseñor in Chapter 41 prepared a comprehensive catalog of earthquakes of the world from 1900 to 1999 by relocating systematically many thousands of earthquakes using the ISS and ISC phase data. Their catalog and the phase data they used for location are archived on the attached Handbook CD.

For more rapid dissemination of earthquake information on a global scale, the US National Earthquake Information Service (NEIS) of the US Geological Survey (in Golden, Colorado) issues results based on its own network of stations as well as phase readings sent by other stations. Visit their Web site at <http://neic.usgs.gov/>. Earthquake parameters for significant earthquakes are usually announced within about one hour, and summaries (now in computer files) are distributed on a weekly basis. The data collected by the NEIS are sent to the ISC for further analysis, as described in the preceding paragraph.

Moment tensor solutions for earthquakes of $M \geq \sim 5.5$ worldwide have been determined by the Harvard group since 1976 (see <http://www.seismology.harvard.edu/projects/CMT/>), and by the USGS since 1981 (see Chapter 50 by Sipkin). Preliminary solutions are produced within minutes after the NEIC's QED results. In addition to Harvard and USGS, there are several centers that determine moment tensor solutions (mostly for regional earthquakes) in near real time.

Most seismic observatories issue their own bulletins, and many national agencies publish national earthquake catalogs. However, their quality and contents vary greatly. The efforts

in seismic monitoring in many countries can be found in their national reports (summarized in Chapter 79 edited by Kisslinger and presented in full on the attached Handbook CD). See also Chapter 87 edited by Lahr and van Eck for a global inventory of seismographic networks.

5. The Nature of Seismic Monitoring of Damaging Earthquakes

Seismic monitoring of earthquakes has been most successful on the global scale because there are (1) organizations (e.g., FDSN, IRIS, ISC, IASPEI, and CTBTO) that promote it, (2) hundreds of academic users, and (3) several major and/or damaging earthquakes every year in the world that draw public and academic attention. Field work is mostly cooperative, with a central organization supplying (or augmenting) the latest equipment, and the labor cost per station is a relatively small amount that can easily be absorbed by a cooperating local institution. On the other hand, seismic monitoring on a regional or local scale is far more difficult because there are only a few academic users, and usually no significant or destructive earthquakes occur for decades in most geographical areas.

5.1 Requirements for Station Site and Spacing

The station site and spacing requirements for seismological research are very different from those for earthquake engineering purposes. Seismologists (especially those who study Earth structure) want their stations to be located at quiet sites, as far away from any human activities as possible. On the other hand, earthquake engineers want instruments in the built environment of urban areas. Since the occurrence of major earthquakes in a given region is rare, we can understand why most seismologists would be reluctant to wait for decades for a few strong-motion records.

Studies indicate that we may need a station spacing of about 1 km or less in order to reduce the observed variances in strong ground motion to a factor less than 2 (Field and Hough, 1997; Evans, 2001). During 1991–1996, the Taiwan government deployed about 1200 accelerographs (at 640 free-field sites with a station spacing of 3–5 km, and in 56 buildings and bridges) nonuniformly in the urban areas of Taiwan (see Chapter 64 by Shin *et al.*). After the 1995 Kobe earthquake, the Japanese government deployed the 1000-station K-Net (see Chapter 64 by Kinoshita) at a uniform spacing of 25 km over Japan. In both cases, the total cost to deploy one station was about \$30 000. Therefore, to achieve 1 km spacing in *one* major urban area would require a few thousand accelerograph stations, and would cost about one hundred million dollars to deploy. However, a more cost-effective alternative would be to selectively deploy strong-motion instruments at fewer sites that are representative of the local site conditions, rather than uniformly throughout an area.

In regard to strong-motion instrumentation needs of the United States, Borchardt *et al.* (1997) derived estimates based on the National Seismic Hazard Maps, population exposure, and knowledge of the distribution of local geologic deposits. These estimates as reviewed and expanded to include the built environment provided the basis for consensus of a national workshop (Stepp, 1997). The estimates indicated that at least 7000 sites were needed to record strong ground shaking with station spacing for rock sites less than 7 km and preferably about 1.7 km in densely urbanized areas, such as San Francisco, California. Workshop consensus indicated that an additional 13 000 stations are needed to ensure that the next major earthquake is thoroughly documented on the built environment, with 7000 for buildings, 3000 for lifelines such as bridges and pipelines, and 3000 for critical facilities necessary for emergency response and near real time disaster assessment.

5.2 Total Cost

There are a number of costs associated with establishing and operating a seismic network: (1) deployment, (2) maintenance and operation, and (3) staffing. We should be aware that the deployment cost must include the capital cost for instruments (including equipment for telemetry, if any), and expenses for siting, site preparation, quality assurance, and administrative overhead in procurement and management. In both the recent Taiwan and Japan cases, the instrumentation cost was about 1/3 of the total deployment cost. Maintenance costs vary, but experience has shown that at least 20% of the instrument cost should be budgeted for parts, supplies, and repair services *every year* for satisfactory performance. Operating costs depend mostly on the telemetry method used for getting the data from the field to the headquarters, and vary greatly in different locations. Staffing costs for maintenance, operation, and research are most difficult to estimate and control over a long period of time. Therefore, the instrument cost is relatively minor in a project that must continue for *decades*.

Because governments and academics usually fund capital equipment out of the same budget, there is a tendency for some seismologists to regard inexpensive instruments as a panacea.⁸ Experience has shown that the instrument cost constitutes only about 10% of the total project cost in 30 years, the length of time that is usually needed to accumulate some significant earthquake data in a high-seismicity area.

What one may do with four different levels of capital funding will be discussed next. Capital funding means a sufficient funding for the total deployment cost in the field and the cost for setting up a headquarters with a staff.

5.3 Very Low Capital Funding at \$50 000

At this very low capital funding level, one may purchase a single low-end digital broadband system to monitor teleseisms, and

operate it as a global seismic station. See Chapter 20 by Hutt *et al.* for more technical details. Deployment cost will be low if one simply installs it in the basement of one's building. Maintenance and operating cost will be low also, but a few thousand dollars per year are necessary for supplies and unexpected repairs. A part-time staff member is needed, but an existing staff member can usually serve in that capacity.

5.4 Low Capital Funding at \$500 000

At this low capital funding level, one may consider setting up a ten-station telemetered network using digital accelerographs to cover an area of about 3000 km² at a station spacing of about 25 km. If the accelerograph allows four channels, then one would just add a vertical-component, short-period seismometer. However, if only three-component instruments are used, then to increase the number of detectable earthquakes one should replace the vertical-component accelerometer by a vertical-component, short-period seismometer (since engineers are interested mostly in the horizontal ground motions). Real-time telemetry may be achieved by leased telephone lines, radios, or satellites. If real-time performance is not needed, then it is cheaper to use the Internet or dial-up access, if they are available in the field. A few companies are selling this type of seismic network with a central processing system to monitor regional and local earthquakes and to provide some coverage for strong ground motion. Deployment cost will be highly dependent on where the network is to be located. The same is true for maintenance, operation, and staffing. One will need at least \$100 000 per year to maintain and operate this kind of network, with at least one full-time staff member.

5.5 Medium Capital Funding at \$5 000 000

At this level of capital funding one may consider setting up, for example: (1) a 100-station telemetered network using digital accelerographs to cover an area of about 10 000 km² at a station spacing of about 10 km, with the modification described in Section 5.4, for monitoring a modest area of high earthquake hazards; and (2) a few global broadband stations for academic research. There is always a trade-off between the area covered and the station spacing. Real-time telemetry may be by leased telephone lines, radios, or satellites. If real-time performance is not needed for all the stations, then one can make use of the Internet or dial-up connections, if available. Alternatively, one could set up a 100-station telemetered broadband network at a larger station spacing to cover more area, and supplement it with telemetered accelerometer signals and/or dial-up accelerographs. Deployment cost will be highly dependent on where the network is located. The same is true for maintenance and operation. One will need at least \$1 000 000 per year and several full-time staff members to maintain and operate such a network.

5.6 High Capital Funding at \$50 000 000

At this high capital cost, one may consider an instrumentation program similar to the TriNet in southern California (see Chapter 78 by Hauksson, *et al.*), the 1000-station K-Net in Japan (Chapter 63 by Kinoshita), or the Taiwan program (Chapter 64 by Shin, *et al.*). The annual budget for staff (10 or more), maintenance, and operation is typically a few million dollars or more, depending on many factors.

5.7 Remarks

It is important to do planning in advance and to visit some well-established seismic networks before one embarks on an instrumentation project. One must be clear as to what objectives can be accomplished within the expected long-term funding situation. This will also help to decide which option of the trade-offs discussed above is preferable. Some guidance in this respect is given in Bormann (2002). Experience indicates that, technically, telemetry is the weakest link in any telemetered seismic network, especially during and after a major earthquake. Therefore, the field units should have some on-board recording capabilities so that important data can be retrieved later if necessary. Some redundancy in the field units, alternative methods of telemetry, and backup data acquisition systems are absolutely necessary.

6. Some Difficulties in Seismic Monitoring for Hazard Mitigation

The major problem in seismic monitoring, especially for hazard mitigation on a long-term basis, is not technical but political and financial. Adequate funding over decades is necessary for the success of a seismic monitoring project. Major earthquakes may not be damaging if they occur in uninhabited or lightly populated areas. However, an earthquake need not be very large in magnitude to cause serious damage if it occurs in a heavily populated area, especially if the earthquake's focal depth is shallow. According to Munich Reinsurance Company (2000), economic losses due to earthquakes in the 20th century are very large. For example, the five largest losses are \$100 billion for the 1995 Kobe (Japan) $M_W = 6.9$ earthquake; \$44 billion for the 1994 Northridge (USA) $M_W = 6.7$ earthquake; \$14 billion for the 1999 Chi-Chi (Taiwan) $M_W = 7.6$ earthquake; \$14 billion for the 1988 Armenia $M_W = 6.7$ earthquake; and \$12 billion for the 1999 Turkey $M_W = 7.6$ earthquake. Note that three of these five earthquakes are not called "major" earthquakes, because their magnitudes are below 7.

6.1 What Seismograms are Most Important to Engineering Designs?

According to Norm Abrahamson (private communication, 2000), designs of large engineering structures benefit most from

strong-motion records of $M \geq 7$ earthquakes obtained within 20 km of fault ruptures. As of mid-1999, there were only eight such strong-motion records in the world after nearly 70 years of effort in strong-motion monitoring. As discussed in the next subsection, the odds for having an $M \geq 7$ earthquake occurring near a station are rare, and the number of strong-motion instruments at the free-field sites throughout the world was not large until about 1990. The Kocaeli, Turkey, earthquake of 17 August 1999 added five more such records. And the Chi-Chi, Taiwan, earthquake of 20 September 1999 added over 60 such records, thanks to an extensive strong-motion instrumentation program that was completed three years earlier (see Chapter 64 by Shin *et al.*).

6.2 Major Earthquakes are Rare in a Given Region

As noted in Section 2, the average annual number of major ($M \geq 7$) earthquakes worldwide is about 15. Most of the shallow major earthquakes occur in subduction zones off the coast, and large areas of the Earth have few or no earthquakes (see Color Plate 15 of this Handbook). Using the earthquake catalog for major earthquakes from 1900 to 1999 by Engdahl and Villaseñor in Chapter 41, about 32% of the $M \geq 7$ earthquakes of the world occurred on land. If a seismic station is deployed on land (as deployment at sea is very expensive), what is the probability that an $M \geq 7$ earthquake will occur within a radius of 20 km of this station in one year?

A very rough estimate can be derived as follows. Since the total land area of the Earth is about $1.5 \times 10^8 \text{ km}^2$, the probability is then about 4×10^{-5} , assuming that each $M \geq 7$ earthquake is a point source. We can improve this probability by, say, a factor of 10 by placing a seismic station in a known seismically active area based on geological and seismological information. A probability of 4×10^{-4} implies that we must wait about 2500 years for an $M \geq 7$ earthquake to occur within 20 km of the station. Alternatively, we need to deploy about 2500 stations in order for an $M \geq 7$ earthquake to occur within 20 km of one of the stations in one year. Observing potentially large damaging earthquakes at near-field distances will, therefore, require the deployment of many stations, or waiting for a long time, or being very lucky in selecting station locations.

6.3 Extending Observation Offshore is Expensive

As pointed out by T. Utsu (personal communication, 2001), it is important for seismologists to extend observation offshore, because more than 2/3 of all earthquakes occur at sea and some of them can be very damaging to lives and properties on land. An effective means to observe earthquakes at sea is to deploy a cable ocean-bottom seismograph (OBS) system. However, this is very expensive. For example, a cable OBS system including four seismic stations, 150 km of cable, and land

facilities costs about \$25 million according to N. Hamada (personal communication). As of 2001, there were seven cable OBS systems in operation in Japan and their signals are monitored in real time by the regional centers of the Japanese Meteorological Agency (JMA). These data greatly improve the determination of location, especially the focal depth, of off-shore earthquakes in Japan.

6.4 Planning, Management, and Bureaucracy

Good seismic monitoring requires long-term planning and efficient management, but few seismologists have the experience or training necessary for the planning and management tasks. Several related technical and organizational topics are elaborated in Bormann (2002). Seismic monitoring involves deploying and operating seismic instruments in the field. If we wish to be good at it, it pays to study how field operations are conducted, such as military operations in a war (e.g., Sun-Tzu, 1993).⁹ Seismic monitoring also needs good management, and it may be instructive to read two recent books by Andy Grove explaining how Intel became the most successful company in the world in the production of microprocessors (Grove, 1987; 1996).

Since funding for seismic monitoring is almost entirely from governments, we cannot avoid dealing with government bureaucracy. It helps to have some understanding of bureaucracy through reading books on this subject (e.g., Parkinson, 1957).¹⁰ Seismic monitoring requires teamwork, and therefore a good leader. It is of utmost importance to have someone who knows how the bureaucracy operates in a particular organization and country.

6.5 Integration, Reorganization, and Data Loss

Seismic monitoring of earthquakes evolved over the years into three major branches as discussed in Section 3. One recent favored approach is to integrate all seismic monitoring into a single entity called real-time seismology. There are, of course, many advantages in this approach, especially from a management point of view. However, getting a large group of people to work together is by no means easy. Aki in Chapter 5 described an approach of getting people from many disciplines to work together under the Southern California Earthquake Center, and it may serve as a blueprint for integrated earthquake programs elsewhere.

As mentioned before, seismic monitoring is almost entirely funded by governments (directly or indirectly), except for some notable early efforts by nongovernment groups (e.g., the Jesuits as reported by Udias and Stauder in Chapter 3). There is no *bottom line* to speak of for government agencies, since there are no “profits” or “losses.” There is a tendency for staff members to increase according to Parkinson’s law to consume all available funding, and for staff quality to decrease with time as deadwood accumulates, for it is difficult to dismiss civil servants. Consequently, few government institutions can

maintain a high-quality level of seismic monitoring for decades, before going out of existence or being reorganized.¹¹

Each reorganization creates disruption, as new chiefs often have their own agendas and directions. Facing uncertainties in management and funding, the long-term preservation of seismic data has been at the bottom of any priority list in seismology. Millions of seismograms have been poorly kept or were inaccessible, and will soon disappear. This sad status was recognized in the 1970s, but little has been done (Lee *et al.*, 1988).

Major capital investments for seismic instrumentation occur infrequently, usually in response to disastrous earthquakes (e.g., K-Net), or military needs (e.g., WWSSN), or broader programs (e.g., microearthquake networks for earthquake prediction). There is a tendency to spend the new funds on equipment and more staff members, and to ignore the costs of operation and maintenance on a long-term basis. A few modern seismic networks have been idle because of this. It is tempting to buy the latest and most advanced equipment, without realizing the risk involved. It takes time and effort to master the latest pieces of equipment, and some of their new features often do not work well in the field.

7. Discussion

The history of earthquake seismology suggests that major advances take place shortly after accumulation of sufficient amounts of seismic data of a quality that surpasses that of previous data.¹² Major advances in earthquake seismology are expected in the near future because digital seismic data have become widely available on both local and global scales. In addition, advances in computers with increasing computing power at decreasing cost have been important to seismologists for more sophisticated data processing and analysis in order to gain insight from the increasing volume of seismic data collected (see Chapter 22 by Scherbaum; Chapter 85 edited by Snoke and Garcia-Fernandez).

In the 1990s, especially after the 1995 Hyogo-ken Nanbu (Kobe) earthquake, large amounts of funding became available in Japan for digital seismic and other instrumentation. Under the Headquarters for Earthquake Research Promotion, a "Fundamental Seismic Survey and Observation Plan" was carried out in Japan for:

1. Earthquake observations: (a) inland earthquake observation by high sensitivity seismographs (observation of microearthquakes), and (b) inland earthquake observation by broadband seismographs
2. Strong-motion observations
3. Observations of crustal deformation (GPS continuous observation)
4. Survey of inland and coastal active faults

These extensive instrumentation programs have now been completed and the data from the high-sensitivity seismograph

(Hi-Net), nationwide broadband seismograph network (Freesia), and digital strong-motion seismograph (KiK-Net) are effectively distributed in near real time by the National Institute for Earth Science and Disaster Prevention (NIED) via the Internet (<http://www.bosai.go.jp/index.html>).

Extensive strong-motion instrumentation programs (typically with 1000 digital instruments) were implemented in Japan and Taiwan, for example, at costs of several tens of millions of US dollars each (see Chapter 63 by Kinoshita; Chapter 64 by Shin *et al.*). The extensive strong-motion data set recorded during the Chi-Chi (Taiwan) earthquake sequence of 20 September 1999 (Lee *et al.*, 2001) showed that these near-fault data will not only contribute to information needed for earthquake engineering but will also lead to a better understanding of the earthquake process (Lee and Shin, 2001; Teng *et al.*, 2001).¹³

Knowledge about the nature of strong ground motions expected from damaging earthquakes will become increasingly important as urbanization rapidly increases, because the lives and properties of ever greater numbers of people are exposed to seismic hazards (see Chapter 74 by Giardini *et al.*). Utsu in Chapter 42 compiled a list of deadly earthquakes in the world for the past five centuries and it is instructive to view his maps. A great challenge for seismologists will be the continued improvement of seismic monitoring to reduce seismic hazards. In particular, it is now technically possible to implement earthquake early-warning systems as discussed in Lee and Espinosa-Aranda (1998). These systems, in principle, provide lifeline operators and citizens with crucial seconds or minutes of lead time for taking some protective action before the strong shaking of a damaging earthquake begins. However, an earthquake early-warning system is expensive to implement and its benefit is difficult to evaluate.

Last, but not least, seismic arrays optimized to detect nuclear explosions (e.g., LASA and NORSAR) and their impact in the development of earthquake seismology have not been discussed, as readers can consult Chapter 23 by Douglas and Chapter 24 by Richards. Seismologists owe a great deal to the military for its generous support in advancing seismology,¹⁴ although some may question its motives and policies regarding data analysis and exchange.

8. Concluding Remarks

Seismic monitoring of earthquakes is becoming a *big science* (Price, 1963; Weinberg, 1967). For example, the Japanese Fundamental Seismic Survey and Observation Plan had been executed successfully as discussed in Section 7. Two large projects are now underway in the United States: (1) the Advanced National Seismic System (ANSS) to integrate seismic monitoring of earthquakes (see <http://www.anss.org/>), and (2) the USArray, "a continental-scale seismic array to provide a coherent 3D image of the lithosphere and the deeper Earth"

(see <http://www.earthscope.org/>). Since 1996, the Preparatory Commission for the Comprehensive Nuclear Test-Ban Treaty Organization (CTBTO) is establishing global monitoring systems (including seismological) worldwide (visit its website at <http://www.ctbto.org/>) (see also Chapter 24 by Richards).

The most direct argument for governments to support long-term seismic monitoring is to collect some relevant data for hazard mitigation. As noted in Section 6, economic losses from damaging earthquakes in the past decade are about \$200 billion, and future losses will be even greater as rapid urbanization is taking place worldwide. For example, the recent Japanese Fundamental Seismic Survey and Observation Plan (costing several hundred million US dollars) is a direct response to the economic losses of about \$100 billion due to the 1995 Kobe earthquake.

In addition to scientific and technological challenges in observational seismology, seismologists must pay attention to achieving (1) stable long-term funding,¹⁵ (2) effective management and execution, and (3) delivery of useful products to the users. Observational seismologists must have perseverance in order to succeed.¹⁶

Acknowledgments

I owe my seismic training to colleagues at the USGS and at many other institutions. Roger Borchardt and Yi-Ben Tsai convinced me of the importance of monitoring strong ground motion, and I wish to thank them for their patience. I was fortunate to have participated in the large-scale seismic instrumentation program of Taiwan from 1991 to 1996. I thank Tony Shin and his staff at the Central Weather Bureau, Taipei, for being gracious hosts.

I am grateful to Robin Adams, Duncan Agnew, Nick Ambraseys, Doc Bonilla, Dave Boore, Roger Borchardt, Peter Bormann, Ken Campbell, Jim Cousins, John Evans, Jennifer Hele', Porter Irwin, Paul Jennings, Hiroo Kanamori, Carl Kisslinger, Fred Klein, John Lahr, Axel Plesinger, Paul Richards, Johannes Schweitzer, Tony Shakal, Shri Singh, Arthur Snoke, Chris Stephens, Ta-Liang Teng, Yi-Ben Tsai, and Erhard Wielandt for their comments and suggestions on the manuscript. I thank Tokuji Utsu for pointing out the importance of extending seismic networks to offshore zones in seismically active regions, and I am grateful to Nobuo Hamada for supplying information on such efforts in Japan. I also thank Lucy Jones and David Oppenheimer for answering my queries about the Northridge earthquake and the Loma Prieta earthquake, respectively.

Notes

1. Because of low magnification, slow recording speed, and no damping, Milne seismograms are useful only for recording $M \approx 8$ or larger earthquakes. Numerous seismographs were developed beginning in the late 1890s. Mechanical seismographs (e.g., Wiechert) are considered to be the first generation. Electromagnetic seismographs (developed by B. Galitzin in the first decade of the 20th century) are considered the second generation, and dominated the design for the next 60+ years. The third-generation seismographs developed in the 1970s are based on electronic force feedback.
2. Many dedicated individuals kept John Milne's vision alive for 50 difficult years. After Milne's death in 1913, the Shide Circulars were continued as bulletins by the British Association's Seismological Committee (i.e., J. H. Burgess and H.H. Turner). This publication became "The International Seismological Summary" (ISS) in 1922 under the direction of H.H. Turner and was supported by the International Union of Geodesy and Geophysics. After Turner's death in 1930, ISS volumes for 1927 to 1935 were issued by the University Observatory, Oxford. They were then issued by the Kew Observatory, Richmond, for the years 1936 to 1961. The ISS volumes for 1962 and 1963 were issued by the International Seismological Centre (ISC), which was organized in 1964 and continues to this day (Willemann and Storchak, 2001).
3. Earthquake prediction has always been a controversial subject. Proponents and skeptics debate the subject with an intensity comparable to that in religion or politics. Richter (1958, p. 8) wrote, "Prediction of earthquakes in any precise sense is not now possible. Any hope of such prediction looks toward a rather distant future. Cranks and amateurs frequently claim to predict earthquakes. They deceive themselves, and to some extent the public,...." In the 1960s and 1970s, some seismologists claimed that they had good leads for predicting earthquakes, almost all in hindsight. Excitement soon faded because their claims could not be replicated. A few lonely voices even questioned the *usefulness* of a successful earthquake prediction. Nevertheless, earthquake prediction programs did advance earthquake seismology in many areas.
4. The concept of IRIS began in the late 1970s as a series of discussions to advance global seismology. One concern was about the failure of the WWSSN to modernize and

expand using digital technology (Paul Richards, personal communication, 2001).

5. After the 1906 San Francisco earthquake, government officials and civic leaders did not want to study earthquakes—bad for attracting business to the then-developing California (Geschwind, 2001). It was maintained that the *fire* destroyed San Francisco. The “Report of the State Earthquake Investigation Commission” on the 1906 earthquake (Lawson, 1908) in two volumes with an atlas was published by the private Carnegie Institution of Washington in Washington, DC.
6. Information about the location of the Loma Prieta and the Northridge earthquakes took ~ 1 hour and ~ 30 min, respectively, to reach the media and the public, although the locations were determined by the real-time systems quickly. According to David Oppenheimer (personal communication, 2001), “We lost A/C power and could not report out the solution [of the Loma Prieta earthquake location by the real-time system] to terminals or pagers.” According to Lucy Jones (personal communication, 2001), the real-time system did not page the results because it flagged the location as a probable telemetry glitch in the Northridge case.
7. The amount of seismic data is *large* from the seismologists’ point of view, but is *small* in comparison with that in many other disciplines. Unfortunately, most seismologists do not pay much attention to data archiving and, as a result, most seismograms and seismic data more than 20 years old are difficult to access. Current technology in computer storage can easily handle terabytes of data, but all storage media have finite lives and must be renewed in order to save the data permanently.
8. Some seismologists believe that it is cheaper to design and build your own instruments than to buy commercial ones. There is no doubt that designing and building an instrument oneself is instructive and useful for learning. It is also necessary in some cases to develop one’s own instruments for certain applications when there are none available commercially. The argument that one needs only about 1/5 of the cost of a commercial instrument to buy the parts and that therefore one would save a lot of money, is false. By the time a prototype instrument is built and works in the field, it will usually cost more than the comparable commercial product when the salaries and overheads are taken into account.
9. Sun-Tzu was a general in the Kingdom of Wu (514–496 BC) in China. He gained an audience with the King by presenting his “Art of War.” He had a distaste of war and urged using military action only as a last resort. He argued that the *cost* of military actions would always be expensive and questioned whether there would be any *financial* gains even if successful. He emphasized strategy, logistics, and discipline in the battle field. The “Art of War” has been widely circulated since his time, and bamboo strips containing it (dated about 200 BC) were discovered in 1974 in an ancient tomb.
10. C.N. Parkinson made a remarkable discovery that the number of subordinates in a government agency multiplies at a rate of 5–7% of the total staff per year, regardless of need. He used the staffing data from the British Admiralty and other British bureaus.
11. For example, the responsibility for earthquake monitoring in the United States government has already changed hands four times in less than a century—it began at the Weather Bureau in 1914, moved to the US Coast and Geodetic Survey in 1925, merged into the Environmental Science Services Administration (ESSA) and then the National Oceanic and Atmospheric Administration (NOAA) in the 1960s, and merged into the US Geological Survey (USGS) in the early 1970s. USGS, itself, narrowly escaped being eliminated by the US Congress in the mid-1990s.
12. For example, shortly after a few hundred seismographs were established around the world in the early 1900s, the gross structure of the Earth’s interior was quickly established by the 1930s. The establishment of the World Wide Standardized Seismograph Network in the early 1960s enabled the study of global seismicity and focal mechanisms on a scale that was previously impossible. As a result, earthquake seismology made significant contributions to the development of the theory of plate tectonics in the late 1960s.
13. After the 1989 Loma Prieta earthquake, Yi-Ben Tsai realized the values of strong-motion records for correlating ground shaking with structural damage. In a visit to Taiwan, he met Dr. Ching-Yen Tsay, the then new Director-general of the Central Weather Bureau and proposed an extensive strong-motion instrumentation program in the urban areas of Taiwan. Dr. Tsay enthusiastically accepted the proposal and persuaded Dr. Chan-Hsuan Liu, the then Minister of Transportation and Communication to incorporate it as a part of the Six-year National Construction Programs, being planned at that time. An advisory board (chaired by Ta-Liang Teng) was established for the detailed planning and execution of the strong-motion instrumentation program, and subsequently a budget of about US \$72 million was authorized by the Taiwan Legislature in 1991. I spent full time working in this program as an invited advisor, on loan from the USGS. This instrumentation program was completed slightly ahead of schedule in 1996 and for a little over US \$40 million. Its successful completion was due largely to the efficient execution by Tony Shin and his staff at CWB, and

to a small extent to my desire to retire from the USGS in 1995. None of us expected that a major earthquake of magnitude 7.6 would occur so soon in Taiwan.

14. The following is just a personal case. I joined the Earthquake studies group of the US Geological Survey in 1967. This group had its origin in the Vela-Uniform program of the Defense Advanced Research Projects Agency (DARPA). The simple PC-based real-time system I developed in the 1980s (Lee, 1994) was a by-product of a project funded by DARPA to conduct experiments in a quarry, and I thank Bob Blandford for his kind support. Its early success was in monitoring volcanic eruptions (e.g., Kerr, 1991; Murray *et al.*, 1996). I was able to modify it quickly for the two key elements of the CWB strong-motion instrumentation program in Taiwan: (1) the RTD system (later refined by Y.M. Wu and his associates at CWB), and (2) the strong-motion array systems deployed in buildings and bridges. This simple PC-based real-time system with reference accelerometers and displacement gauges permitted me to evaluate commercial accelerographs on a shake table quickly, and made it possible to accelerate the procurement of accelerographs and accelerometers for deployment in Taiwan under open-bidding.
15. As pointed out by Duncan Agnew (personal communication, 2001), the funding system has a legitimate bias toward novelty and against doing the same thing as in long-term seismic monitoring. Seismology has to get by with occasional operational needs: whenever there is a damaging earthquake in a populated area, everyone gets very interested, but not for the rest of the time. One solution is for a government to impose a “tax” for funding seismic monitoring in the building permit fees; for example, the California Strong Motion Instrumentation Program has been funded this way.
16. In his Nobel lecture, Abdus Salam (1979) said he gave up experimental physics and started on quantum field theory because he recognized that the craft of experimental physics was beyond him, for “it was the sublime quality of patience—patience in accumulating data, patience with recalcitrant equipment” that he sadly lacked.

Editor's Note

For readers' convenience, two out-of-print books (Lee and Stewart, 1981; Lee, Meyers, and Shimazaki, 1988) are given as PDF files on the attached Handbook CD under the directory \17Lee1.

1. Scope of this Chapter and Historical Notes

1.1 Scope

Seismometry is the technical discipline concerned with the detection and measurement of seismic ground motion. It comprises the design of seismographs, their calibration, their installation, and the quantitative interpretation of seismograms in terms of ground motion. A seismograph basically consists of one or more seismometers, a clock or time-signal receiver, and a recorder. The present chapter concentrates on the theory and usage of seismometers. It does not describe their technical design in detail, but mentions some general design principles. Emphasis is put on precise methods for calibrating and testing. Although most commercial seismometers are well calibrated and normally need not be recalibrated by the user after installation, such methods are essential to ensure that an instrument is in good working condition.

1.2 Inertial and Strain Seismometers

There are two basic types of seismic sensors: *inertial* seismometers, which measure ground motion relative to an inertial reference (a suspended mass), and *strainmeters* or *extensometers*, which measure the motion of one point of the ground relative to another. The wavelength of seismic waves is so large that the differential motion of the ground within a vault is normally much smaller than the motion relative to an inertial reference; strainmeters are therefore generally less sensitive to earthquake signals. However, at very low frequencies it becomes increasingly difficult to maintain an inertial reference, and for the observation of low-order free oscillations of the Earth and tidal signals, strainmeters may outperform inertial seismometers. In the presence of gravity, inertial seismometers with a horizontal sensitive axis also respond to tilt, and the better ones are more sensitive to short-term tilt than the majority of dedicated tiltmeters (although inferior in their

long-term stability). The principles of operation of horizontal seismometers and tiltmeters are identical. Instruments measuring the angular acceleration, although theoretically required for a complete description of ground motion, have not attained any significance in seismology because the rotational component of seismic signals is in general too small to be directly observed. (Even if the signals were strong enough, existing mechanical sensors would not be able to separate them from the associated large displacements.) We will treat only inertial seismometers in this article. Their theory will be presented as far as it is required for an understanding of specifications, calibration procedures, and operational requirements.

In contrast to most other sensors, inertial seismometers have an inherently frequency-dependent response that must be taken into account when the ground motion is restored from the recorded signal. This is because a suspended mass does not represent a perfect inertial reference. When the ground motion is slow, the mass will begin to follow it, and the output signal for a given ground displacement will therefore be diminished. The mechanical system forms a high-pass filter for the ground displacement. Recorders, on the other hand, normally have a constant gain up to some upper cut-off frequency, and contribute only a scale factor to the overall response. We will therefore not discuss their frequency response in detail.

1.3 Historical Seismographs

The term *seismograph* is today reserved for instruments recording the waveform of the ground motion versus time. In that sense, the first seismograph was built in Italy by Cecchi in 1875; it was, however, so insensitive that its first known seismogram dates from 1887. In the meantime, Ewing and colleagues in Japan had built several seismographs (Ewing, 1884) and recorded the first earthquake in 1880. In the same year one of the instruments was tested on a shake table! Von Rebeur-Paschwitz (1889) recognized seismic waves from an earthquake in Japan in the records of his tiltmeters at Potsdam and Wilhelmshaven, giving seismology a global dimension. The early history of seismometry to 1900 is described by Dewey

and Byerly (1969) in an excellent article with many figures and references.

Going back in time, the “electromagnetic seismograph” built by Palmieri in 1856 was little short of being the first seismograph in a modern sense. It had motion-sensitive electric contacts whose closures were recorded on a strip of paper like Morse code. Earlier constructions, which were only designed to indicate the occurrence and direction of a seismic shock, would today be termed *seismoscopes*. The Chinese Chang Heng is reported to have built one in AD 132; models of his jar-shaped instrument are exhibited in many seismological institutes, but its inner mechanism is unknown.

At the beginning of the 20th century, the technical development concentrated on mechanical seismographs with smoke-paper recording. Viscous damping was introduced by Wiechert around 1900. To overcome the remaining solid friction, the mass had to be increased with the square of the magnification. The largest seismographs had masses from 10 to 20 tons, magnifications around 1000, and stable free periods up to 12 sec. Mainka and Wiechert seismographs served in many observatories until after the Second World War, and a few of them are still (or again) operational. De Quervain and Piccard in Zürich (1924, 1927) built a mechanical three-component seismograph with a single mass of 21 tons whose position was stabilized with a water ballast—probably the first feedback-stabilized seismograph. Many of the seismographs of the early 20th century are described in Galitzin’s lectures on seismometry (1914) and in a comprehensive article by Berlage (1932).

Photographic recording was occasionally used from the beginning, but the higher cost and lower quality of the record put the method at a disadvantage, at least until electric light was available. Later it became a practical alternative, for example, with the Wood–Anderson torsion seismograph on which the Richter magnitude scale is based (Anderson and Wood, 1925). The electromagnetic seismograph with galvanometer-photopaper recording, invented by Galitzin as early as 1904, remained for more than half a century the most sensitive long-period seismograph, but it had to wait for gradual improvements by LaCoste, Benioff, Press, Ewing, and Lehner (LaCoste, 1934; Benioff and Press, 1958; Press *et al.*, 1958; Lehner, 1959) before it was stable enough for wide deployment in the WWSSN (World Wide Standardized Seismograph Network; Oliver and Murphy, 1971).

The next generation of electromagnetic seismographs in the HGLP (High-Gain Long-Period) project (Savino *et al.*, 1972) was partially electronic, using galvanometer-phototube amplifiers. The SRO system (Seismic Research Observatory; Peterson *et al.*, 1976) had a fully electronic, broadband, force-balance sensor but did not record the broadband signal. The sensor of the original IDA network (International Deployment of Accelerometers; Agnew *et al.*, 1976, 1986) was a LaCoste–Romberg gravimeter with a slow electrostatic force-balance feedback; although this instrument was not useful as a

general-purpose seismometer, its sensitivity in the free-mode band is unsurpassed. An eyewitness account of the emerging electronic era of seismometry from 1947 on is given by Melton (1981a,b).

In the time of transition from electromagnetic to electronic seismographs between 1960 and 1975, two opposite trends can be observed. As long as visible recording was the standard and magnetic tape recording was not much better, the gain could only be increased when the marine microseisms, at periods around 6 sec, were suppressed. This resulted in the development of high-gain, narrowband seismographs, which were excellent for studying ground noise and monitoring nuclear explosions but were easily saturated by earthquakes. On the other hand, several broadband seismographs with analog or digital magnetic tape recording were developed. They remained experimental because continuous broadband recording and digital or analog post-processing were too inconvenient for routine work. The first digital broadband seismograph was operated at the California Institute of Technology as early as 1962 (Miller, 1963) with the intention “to preserve the greatest spectrum, dynamic range, and sensitivity.” The installation was discontinued because the digital technology was too inefficient at the time. Block and Moore (1970) built a small broadband quartz accelerometer that was the most sensitive broadband sensor of its time but not a very practical instrument; it required vacuum and a thermostat. An analog very-broadband seismograph was operated in Czechoslovakia from 1972 on (Plešinger and Horalek, 1976); its data archive was later converted to a digital standard format. The first practically successful digital broadband installation is the German GRF array (Harjes and Seidl, 1978; Buttkus, 1986), which has been operational since 1976. The present generation of digital very-broadband seismographs covering the full teleseismic bandwidth including the free-mode band was developed from 1984 on (Wielandt and Steim, 1986).

2. Mechanical Receivers, and Transducers

2.1 The Linear Pendulum

The simplest physical model for an inertial seismometer is a mass-and-spring system with viscous damping (Fig. 1). The mechanical elements are a mass of M kilograms, a spring with a stiffness S (measured in newtons per meter), and a damping element with a constant of viscous friction R (in newtons per meter per second). Let the time-dependent ground motion be $x(t)$, the absolute motion of the mass $y(t)$, and its motion relative to the ground $z(t) = y(t) - x(t)$. An acceleration $\ddot{y}$ of the mass results from any external force f acting on the mass, and from the forces transmitted by the spring and the damper:

$$M\ddot{y} = f - Sz - R\dot{z} \quad (1)$$

FIGURE 1 Damped harmonic oscillator.

Since we are interested in the relationship between z and x , we rearrange this into

$$M\ddot{z} + R\dot{z} + Sz = f - M\ddot{x} \quad (2)$$

Before we solve this equation in the frequency domain, we observe that an acceleration $\ddot{x}$ of the ground has the same effect as an external force of magnitude $f = -M\ddot{x}$ acting on the mass in the absence of ground acceleration. We may thus simulate a ground motion x by applying a force $-M\ddot{x}$ to the mass while the ground is at rest. The force is normally generated by sending a current through an electromagnetic transducer, but it may also be applied mechanically.

2.2 Constraining the Motion

Although the mass-and-spring system of Figure 1 is a useful mathematical model for a seismometer, it is incomplete as a practical design. The suspension must suppress five out of the six degrees of freedom of the seismic mass (translational and rotational) but the mass must still move as freely as possible in the remaining direction. Some instruments achieve this with five tensioned threads or five tangential spokes (Geotech S13, Sensonics Mk III). In geophones, the seismic mass is normally suspended between labyrinth springs (which are stamped out of a circular elastic membrane). Most long-period suspensions are of the pendulum type, where the seismic mass rotates around a virtual axis defined by flexural hinges (Figs. 2–4). The point bearings shown in Figures 2 and 3 are for illustration only; crossed flexural hinges are normally used.

In principle it is also possible to let the mass move in all directions and observe its motion with three orthogonally arranged transducers, thus creating a three-component sensor with only one suspended mass. Indeed, some historical instruments have made use of this concept. However, it is difficult to reduce the restoring force and to suppress parasitic rotations of the mass when its translational motion is mechanically unconstrained. Modern three-component seismometers

FIGURE 2 (a) Garden-gate suspension. (b) Inverted pendulum.

FIGURE 3 Lacoste suspensions.

FIGURE 4 Leaf-spring astatic suspensions.

therefore have separate mechanical sensors for the three axes of motion.

2.3 Pendulum Type Seismometers

These are sensitive not only to translational but also to angular acceleration. The rotational component of seismic shear waves is, however, too small to have a noticeable effect; its contribution to the output signal is of the order kl , where k is the horizontal wavenumber and l the length of the pendulum (Rodgers, 1969). In technical applications or on a shake table, effects of rotation may be noticeable.

For small translational ground motions, the equation of motion of a rotational pendulum is formally identical to Eq. (2) but z must then be interpreted as the angle of rotation. Since the rotational equivalents to the constants M , R , and S in Eq. (2) are of little interest in modern force-balance seismometers, we will not discuss them further and refer the reader instead to the older literature (Berlage, 1932).

2.4 Sensitivity of Horizontal Seismometers to Tilt

We have already seen [Eq. (2)] that a seismic acceleration of the ground has the same effect on the seismic mass as an external force. The largest such force is gravity. It is normally canceled by the suspension, but when the seismometer is tilted, the projection of the vector of gravity onto the axis of sensitivity changes, producing a force that is in most cases indistinguishable from a seismic signal. The effect is of second order (proportional to the square of the tilt) and therefore small in well-adjusted vertical seismometers but otherwise of first order. It not only modifies the amplitude with which the horizontal components of long-period *SV* and Rayleigh waves are recorded (Rodgers, 1968) but also introduces noise when the ground is tilted by moving or variable surface loads (traffic, people, wind, barometric pressure). Sensitivity to tilt is the reason why horizontal long-period seismic traces are generally noisier than vertical ones.

A short, impulsive tilt excursion is equivalent to a steplike change of the ground velocity and to a ramplike displacement. It will therefore cause a long-lasting transient in horizontal broadband seismograms. In the near field of a seismic source, the tilt has the same waveform as the displacement. The tilt signal can then be predicted from the vertical trace and removed from the horizontal traces (Wielandt and Forbriger, 1999).

2.5 Decreasing the Restoring Force

At low frequencies and in the absence of an external force, Eq. (2) can be simplified to $Sz = -M\ddot{x}$ and read as follows: A relative displacement of the seismic mass by $-\Delta z$ indicates a ground acceleration of magnitude

$$\ddot{x} = \frac{S}{M} \Delta z = \omega_0^2 \Delta z = \left(\frac{2\pi}{T_0}\right)^2 \Delta z \quad (3)$$

where ω_0 is the angular eigenfrequency of the pendulum and T_0 is its eigenperiod. If Δz is the smallest displacement that can be measured electronically, then the formula determines the smallest low-frequency ground acceleration that can be observed. For a given transducer, it is inversely proportional to the square of the free period of the suspension. A sensitive long-period seismometer therefore requires either a pendulum with a low eigenfrequency or a very sensitive transducer (for quantitative examples, see Section 5.2). Since the eigenfrequency of an ordinary pendulum is essentially determined by its size, and seismometers must be reasonably small, astatic suspensions have been invented that combine small overall size with a long free period.

The simplest astatic suspension is the “garden-gate” pendulum used for horizontal seismometers (Fig. 2a). The mass moves in a nearly horizontal plane around a nearly vertical axis. Its free period is the same as that of a mass suspended

from the point where the plumb line through the mass intersects the axis of rotation. The period is infinite when the axis is vertical, and is usually adjusted by tilting the whole instrument. This is one of the earliest designs for long-period horizontal seismometers.

Another early design is the inverted pendulum held in stable equilibrium by springs or by a stiff hinge (Fig. 2b); a famous example is Wiechert’s horizontal pendulum built around 1905 (Berlage, 1932).

An astatic spring geometry for vertical seismometers was invented by LaCoste (1934) (Fig. 3a). The mass is in neutral equilibrium when three conditions are met: the spring is prestressed to zero length (i.e., the spring force is proportional to the total length of the spring), its end points make a right angle from the hinge, and the mass is balanced in the horizontal position of the boom. A finite free period is obtained by making the angle slightly smaller, or by tilting the frame accordingly. By simply rotating the pendulum, astatic suspensions with a horizontal or oblique axis of sensitivity can also be constructed (Fig. 3b).

The astatic leaf-spring suspension (Fig. 4a) used in the STS1 seismometer (Wielandt, 1975; Wielandt and Streckeisen, 1982) has a limited range around its equilibrium position compared to a LaCoste suspension, but is much simpler to manufacture. A similar spring geometry is also used in the triaxial seismometer STS2 (Fig. 4b). The delicate equilibrium of forces in astatic suspensions makes them susceptible to external disturbances such as changes in temperature; they are difficult to operate without a stabilizing feedback system.

Apart from genuinely astatic designs, almost any seismic suspension can be made astatic with an auxiliary spring acting normal to the line of motion of the mass and pushing the mass away from its equilibrium; the Sensonics Mk III seismometer is an example. The long-period performance of such suspensions is, however, quite limited. Neither the restoring force of the original suspension nor the destabilizing force of the auxiliary spring can be made perfectly linear (i.e., proportional to the displacement). While the linear components of the force may cancel, the nonlinear terms remain and cause the oscillation to become anharmonic and even unstable at large amplitudes. Viscous and hysteretic behavior of the springs may also cause problems. The additional spring (which has to be soft) may introduce parasitic resonances. Modern seismometers do not use this concept and rely for their sensitivity either on a genuinely astatic spring geometry or on the sensitivity of electronic transducers.

2.6 Effects of Temperature and Pressure

The equilibrium between gravity and the spring force in a vertical seismometer is disturbed when the temperature changes. Although thermally compensated alloys such as Elinvar are available for springs, a self-compensated spring does not make a compensated seismometer. The geometry of the whole

suspension changes with temperature; the seismometer must therefore be compensated as a whole. However, the different time constants involved prevent an efficient compensation at seismic frequencies. Short-term changes of temperature must therefore be suppressed by thermal insulation. Special caution is required with active seismometers: they heat themselves up when insulated and are then very sensitive to air drafts, so the insulation must suppress any possible convection. Long-term (seasonal) changes of temperature do not interfere with the seismic signal, but may drive the seismometer out of its operating range. Equation (3) can be used to calculate the thermal drift of a passive vertical seismometer when the temperature coefficient of the spring force is formally assigned to gravity.

Fluctuations of the barometric pressure (resulting from turbulent convection in the atmosphere) have multiple effects on seismic sensors. When the sensor is not sealed, its mass experiences a variable buoyancy. This is a large effect that is intolerable in a vertical broadband seismometer. Changes of pressure also disturb the temperature of the sensor even if it is thermally isolated. On the other hand, a sealed enclosure may be deformed by the barometric pressure and transmit stresses or tilt. The enclosure must therefore either be very rigid or mechanically decoupled from the sensor (see Section 6.2). Even when the sensor is perfectly shielded, there remain some effects of the barometric pressure that are independent of the sensor: ground tilt due to atmospheric loading, often enhanced by cavity effects (Beauduin *et al.*, 1996); the gravitational attraction of the atmosphere (Zürn and Widmer, 1995); and the continuous excitation of free modes by global atmospheric turbulence (Tanimoto, 1999). Only the first two effects are of local origin and can partially be removed by a correction for the local barometric pressure.

2.7 The Homogeneous Triaxial Arrangement

In order to observe ground motion in all directions, a triple set of seismometers oriented toward East, North, and upward (Z) has been the standard for a century. However, horizontal and vertical seismometers differ in their construction, and it costs some effort to make their responses equal. An alternative way of manufacturing a three-component set is to use three sensors of identical construction whose sensitive axes are inclined against the vertical like the edges of a cube standing on its corner (Fig. 5), by an angle of $\arctan \sqrt{2}$, or 54.7° .

Presently only one commercial seismometer, the STS2, makes use of this concept, although it was not the first one to do so (Melton and Kirkpatrick, 1970). Since most seismologists want finally to see the conventional E , N , and Z components, the oblique components U , V , W of the STS2 are electrically recombined according to

$$\begin{pmatrix} X \\ Y \\ Z \end{pmatrix} = \frac{1}{\sqrt{6}} \begin{pmatrix} -2 & 1 & 1 \\ 0 & \sqrt{3} & -\sqrt{3} \\ \sqrt{2} & \sqrt{2} & \sqrt{2} \end{pmatrix} \begin{pmatrix} U \\ V \\ W \end{pmatrix} \quad (4)$$

FIGURE 5 Geometry of the homogeneous triaxial seismometer STS2.

The X and Y axes are normally oriented toward E and N . Noise originating in one of the sensors of a triaxial seismometer will appear on all three outputs (except for Y being independent of U). Its origin can be traced by transforming the X , Y , and Z signals back to U , V , and W with the inverse (transposed) matrix. Disturbances affecting only the horizontal outputs are unlikely to originate in the seismometer, and are in general due to tilt.

2.8 Electromagnetic Velocity Sensing and Damping

The simplest transducer both for sensing motions and for exerting forces is an electromagnetic (electrodynamical) device where a coil moves in the field of a permanent magnet, as in a loudspeaker. Motion induces a voltage in the coil; a current flowing in the coil produces a force. From the conservation of energy it follows that the responsivity of the coil-magnet system as a force transducer, in newtons per ampere, and its responsivity as a velocity transducer, in volts per meter per second, are identical. The units are in fact the same (remember that $1 \text{ Nm} = 1 \text{ J} = 1 \text{ V A sec}$). When such a transducer is loaded with a resistor and thus a current is permitted to flow, it generates a force opposing the motion according to Lenz's law. This effect is used to damp the mechanical free oscillation of passive seismic sensors (geophones).

In comparison to technical vibrations, the seismic ground motion is slow and small most of the time. The signals delivered by electromagnetic velocity transducers are therefore normally quite small. For maximum sensitivity, the input stage of the electronic amplifier must be matched to the impedance of the coil (or vice versa). The matter is treated in detail by Riedesel *et al.* (1990), Rodgers (1992), and Rodgers (1993).

2.9 Electronic Displacement Sensing

At very low frequencies, the output signal of electromagnetic transducers becomes too small to be useful for seismic sensing. One then uses active electronic transducers where a carrier signal, usually in the audio frequency range, is modulated by the motion of the seismic mass. The basic modulating device is an inductive or capacitive half-bridge. Inductive half-bridges are detuned by a movable magnetic core. They require no electrical connections to the moving part and are environmentally robust; however, their sensitivity appears to be limited by the granular nature of magnetism, and they may push back on the seismometer mass. Capacitive half-bridges are realized as three-plate capacitors where either the central plate or the outer plates move with the seismic mass. Their sensitivity is limited by the ratio between the electric field strength and the electronic noise of the demodulator; it is typically a hundred times better than that of the inductive type. The comprehensive paper of Jones and Richards (1973) on the design of capacitive transducers still represents the state of the art in all essential aspects.

3. Mathematical Representation of the Response

3.1 The Transfer Function

We can give here only a very brief outline of the theory of linear systems. The reader who is not familiar with it should consult a textbook such as Oppenheim and Willsky (1983); for digital signal processing, Oppenheim and Schaffer (1975) is a standard text. An instructive book on the Fourier transformation and its applications is that of Bracewell (1978). Seismological applications of the theory are treated in Plešinger *et al.* (1996) and in Scherbaum (1996).

Seismometers, amplifiers, and filters are designed as linear and time-invariant systems, i.e., the mathematical relationship between the time-dependent input and output signals is supposed to be a linear differential equation with constant coefficients. This has the mathematical consequence that sinusoidal input signals produce sinusoidal output signals. The response of such a system can be described by a complex gain factor T at each frequency: When the input signal is $x(t) = X e^{j\omega t}$ and the output signal is $z(t) = Z e^{j\omega t}$, then the gain is $T = Z/X$. It may have a physical dimension (when the system is a transducer) and will in general depend on frequency. The function $T(\omega)$ is called the *complex frequency response*. Its absolute value $|T(\omega)|$ is the *amplitude response* and its phase is the *phase response* of the system. Signals of arbitrary time dependence can be represented as an integral or sum over sinusoidal signals of different frequency; knowledge of the response function $T(\omega)$ at all relevant frequencies is therefore sufficient to calculate the response of the system to any input signal. The decomposition of arbitrary signals into sinusoidal

(time-harmonic) components is a *Fourier transformation*, and their synthesis from such components is an *inverse Fourier transformation*. For transient signals such as analog seismograms, the Fourier transformation is formulated as a pair of integral transformations:

$$\begin{aligned} f(t) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} a(\omega) e^{j\omega t} d\omega, \\ a(\omega) &= \int_{-\infty}^{\infty} f(t) e^{-j\omega t} dt \end{aligned} \quad (5)$$

The most general class of signals for which the response of a linear and time-invariant system can be described by a gain factor are sinusoidal oscillations with exponentially growing or decaying amplitudes: $a(t) = A e^{st}$ with complex $s = \sigma + j\omega$. (The complex exponential function is defined as $e^{(\sigma + j\omega)t} = e^{\sigma t}(\cos \omega t + j \sin \omega t)$). Again the system can be characterized by a complex gain factor $H(s)$: The input signal $x(t) = X e^{st}$ produces the output signal $z(t) = Z e^{st} = H(s) X e^{st}$, thus $Z = H(s) X$. Other signals are decomposed and synthesized with the *Laplace transformation*:

$$\begin{aligned} f(t) &= \frac{1}{2\pi j} \int_{\sigma - j\infty}^{\sigma + j\infty} b(s) e^{st} ds \quad \text{for } t > 0 \\ b(s) &= \int_0^{\infty} f(t) e^{-st} dt \end{aligned} \quad (6)$$

The Fourier transformation may be considered as a special case of the Laplace transformation with a purely imaginary $s = j\omega$, although the mathematical concepts behind the two transformations are somewhat different. $H(s)$ is the *transfer function* of the system. It follows that $T(\omega) = H(j\omega)$; the functions $T(\omega)$ and $H(s)$ are related by a simple substitution of the frequency variable but are not identical. When their poles and zeros or other mathematical properties are discussed, it is important to state which one of the two functions is meant. The terminology is, however, not uniform in the literature; sometimes $T(\omega)$ is also referred to as a transfer function.

Transfer functions of seismometers and also of a wide class of other mechanical and analog electronic systems are rational functions of frequency with real coefficients: $H(s) = P(s)/Q(s)$, where $P(s)$ and $Q(s)$ are polynomials in s . This is a consequence of the fact that the differential equation of the system is transformed into an algebraic equation for the complex signal amplitudes when only signals with a time dependence of the form e^{st} or $e^{j\omega t}$ are admitted; Eq. (8) in the next paragraph is an example. A polynomial $P(s)$ is up to a factor determined by its zeros, i.e., by those complex values of s for which $P(s) = 0$. The zeros of $P(s)$ are at the same time those of $H(s)$; the zeros of $Q(s)$ are poles of $H(s)$. Rational transfer functions can therefore be specified with a limited number of numerical coefficients, by listing either the complex poles and zeros or the real polynomial coefficients. Different factorizations of the polynomials are possible in the latter case.

The essential options are:

1. The poles and zeros in the complex s plane are listed, together with a constant gain factor.
2. The polynomial coefficients of the nominator and denominator are listed (they are real when $s = j\omega$ is chosen as the frequency variable).
3. The polynomials are decomposed into normalized first- and second-order factors, each of which is defined by its corner frequency and, in case of second order, numerical damping. The individual factors can normally be attributed to physical subunits of the system. An overall gain factor is also required.

3.2 The Frequency Response of Geophones

Using time-harmonic signals, the solution of the differential equation (2) becomes very simple. Let the input signal be $x(t) = Xe^{j\omega t}$, the output signal $z(t) = Ze^{j\omega t}$, and the external force $f(t) = Fe^{j\omega t}$. Equation (2) then reduces to

$$(-\omega^2 M + j\omega R + S)Z = F + \omega^2 MX \quad (7)$$

$$Z = \frac{F/M + \omega^2 X}{-\omega^2 + j\omega R/M + S/M} \quad (8)$$

The mechanical pendulum is thus a second-order high-pass filter for displacements, and a second-order low-pass filter for accelerations and external forces. Its angular corner frequency is $\omega_0 = \sqrt{S/M}$. At this frequency, the ground motion X is amplified by a factor $\omega_0 M/R$ and phase shifted by $\pi/2$. The imaginary term in the denominator is usually written as $2j\omega\omega_0 h$, where $h = R/(2\omega_0 M)$ is the numerical damping, i.e., the ratio of the actual to the critical damping.

In order to convert the motion of the mass into an electrical signal, the mechanical pendulum is in the simplest case coupled with an electromagnetic velocity transducer (see Section 2.8) whose output voltage we denote by E . We then have an electromagnetic seismometer, also called a geophone when designed for seismic exploration. When the responsivity of the transducer is σ ($\text{V m}^{-1} \text{sec}^{-1}$; $E = \sigma j\omega Z$) we get

$$E = \frac{j\omega\sigma(F/M + \omega^2 X)}{-\omega^2 + 2j\omega\omega_0 h + \omega_0^2} \quad (9)$$

from which, in the absence of an external force, we obtain the complex response functions

$$T_d = \frac{E}{X} = \frac{j\omega^3 \sigma}{-\omega^2 + 2j\omega\omega_0 h + \omega_0^2} \quad (10)$$

for the displacement;

$$T_v = \frac{E}{j\omega X} = \frac{\omega^2 \sigma}{-\omega^2 + 2j\omega\omega_0 h + \omega_0^2} \quad (11)$$

for the velocity; and

$$T_a = \frac{E}{-\omega^2 X} = \frac{-j\omega\sigma}{-\omega^2 + 2j\omega\omega_0 h + \omega_0^2} \quad (12)$$

for the acceleration. The geophone is a second-order high-pass filter for the velocity, and a bandpass filter for the acceleration.

We have so far treated the damping as if it were a viscous effect in the mechanical receiver. Actually, only a small part h_m of the damping is due to mechanical causes. The main contribution normally comes from the electromagnetic transducer, which is suitably shunted for this purpose (see Section 2.8). Its contribution is

$$h_{el} = \frac{\sigma^2}{2M\omega_0 R_d} \quad (13)$$

where R_d is the total damping resistance (the sum of the resistances of the coil and of the external shunt). The total damping $h_m + h_{el}$ is preferably chosen as $1/\sqrt{2}$, a value that defines a second-order Butterworth filter characteristic, and gives a maximally flat response in the passband.

3.3 The Impulse Response

Alternatively, the transfer properties of a seismometer can be described in the time domain by its impulse response, which is the response of the system to an impulsive input signal. (An impulse in this sense is any signal whose time integral is undistinguishable from a unit step.) The impulse response and the transfer function are Laplace transforms of each other, so they offer mathematically equivalent descriptions of the system. In the same way, the complex frequency response is the Fourier transform of the impulse response. The impulse response can directly be calculated from the poles and zeros of the transfer function. For a practical specification, the impulse response is less suitable because it is a transcendental function of infinite duration that is inconvenient to formulate.

The response of a seismograph to an arbitrary input signal can in principle be computed as the convolution of that signal with the impulse response. However, due to the infinite length of the latter, this may not be an efficient procedure. Also, a sampled version of the impulse response may not represent the analytical form correctly when the system is not strictly band-limited. So computing the response of a system by convolution requires some precautions, and one would in most cases prefer either to do the computation in the frequency domain with the Fourier transformation, or to filter the input signal with a recursive filter that represents the seismograph, as explained in the next paragraph.

3.4 Representing a Seismograph by a Recursive Filter

For a general theory of recursive (or IIR) filters, we must refer the reader to the pertinent literature (Oppenheim and Schaffer,

1975; Robinson and Treitel, 1980; Plešinger *et al.*, 1996). For mathematical reasons, recursive filters can only approximate, but not have, the rational transfer functions of seismographs. In a restricted sense, however, an exact equivalent exists. When we filter all signals with an antialias filter that has a rational transfer function and is sharp enough to practically prevent aliasing, then we can precisely model the overall transfer function with an “impulse-invariant” recursive algorithm (Schuessler, 1981). Remarkably, the rational antialias filter need not exist in hardware but only as part of the computer algorithm. So we can, in effect, precisely model any seismograph in a bandwidth that is by a factor of 2 or so smaller than theoretically permitted by the sampling theorem. Even this restriction can be overcome by sampling the signals twice as fast, or by resampling them numerically. The method is especially useful for the purpose of calibrating seismographs with arbitrary signals (see Section 9).

4. Force-Balance Accelerometers and Seismometers

4.1 The Force-Balance Principle

The precision of a conventional, passive seismometer depends on its two functional subunits: the mechanical suspension and the displacement or velocity transducer. An inertial seismometer basically measures the inertial force acting on the seismic mass in an accelerated local frame of reference [Eq. (2)]. The suspension converts the inertial force into a displacement of the mass, and the transducer converts this into an electrical signal. Neither one of these conversions is inherently precise. As discussed under Section 2.5, a sensitive seismometer must have a suspension with a small restoring force so that small accelerations produce noticeable displacements of the seismic mass. Then, of course, larger seismic signals or environmental disturbances produce large displacements that change the geometry of the spring and destroy the linear relationship between displacement and force. When the restoring force is diminished, undesired effects such as hysteresis and viscous behavior retain their absolute magnitudes and thus become relatively larger. Finally, it is difficult to build linear transducers with a large range. A passive seismic sensor therefore cannot be optimized for sensitivity and precision at the same time.

These problems are well known from the design of precision instruments, especially of laboratory balances. They are solved by compensating the unknown force with a known force, rather than determining it indirectly from the elongation of a spring. The compensating force is generated in an electromagnetic transducer and is controlled by a servo circuit (Fig. 6) that senses the position of the seismic mass and adjusts the force so that the mass returns to its center position. Such a system is most effective when it contains an integrator, in

FIGURE 6 FBA feedback circuit.

which case the offset of the mass is exactly nulled in the time average. Due to unavoidable delays in the feedback loop, servo systems have a limited bandwidth; however, at frequencies where they are effective, they force the mass to move with the ground by generating a feedback force strictly proportional to ground acceleration. When the force is proportional to the current in the transducer, then the current, the voltage across the feedback resistor R_1 , and the output voltage are all proportional to ground acceleration. We have thus converted the acceleration into an electrical signal without relying on the mechanical precision of the spring. The suspension still serves as a detector but not as a converter, and may now be optimized for sensitivity without giving up precision.

The effectiveness of a servo system is measured by its loop gain L , which is the amplitude ratio of the feedback force to the uncompensated residual of the inertial force. If f is the inertial force and r the residual, then $r = f/(1 + L)$. A large loop gain implies a small residual and thus an output signal that represents the acceleration with a small error. The integrator provides a large loop gain and thus a high precision at low frequencies. At high frequencies, the loop gain is limited by stability conditions and cannot be increased arbitrarily; this topic is treated in textbooks on network analysis or system theory (Oppenheim and Willsky, 1983). Some minor modifications of the basic circuit, such as the addition of a small capacitor C parallel to the feedback resistor R_1 , may be required to ensure stability.

The response of a servo system is approximately inverse to the gain of the feedback path. It can easily be modified by giving the feedback path a frequency-dependent gain. For example, if we make the capacitor C large so that it determines the feedback current, then the gain of the feedback path increases linearly with frequency, and we have a system whose responsivity to acceleration is inverse to frequency and thus flat to velocity over a certain passband. We will look more closely at this option in Section 4.3.

4.2 Force-Balance Accelerometers

By equating the inertial and the electromagnetic forces, it is easily seen that in the circuit of Figure 6 the factor of proportionality between the output voltage and the acceleration is

$$A = \frac{MR_1}{\sigma} \quad (14)$$

where M is the seismic mass, R_1 is the resistance of the feedback path (including the coil), and σ is the responsivity of the forcer (in N A^{-1}). The conversion is determined by only three passive components, of which the mass is error-free by definition (it defines the inertial reference), the resistor is a nearly ideal component, and the force transducer can be very precise because the motion is small.

Figure 6 is the circuit of a force-balance accelerometer (FBA), a device that is widely used for earthquake strong-motion recording, measuring tilt, and inertial navigation. Since the dynamic range (see Section 5.1) of a feedback system is mainly determined by its feedback path, which is in this case composed of passive components whose range is not limited by semiconductor noise or clipping, FBAs can have a very large dynamic range (up to 160 dB). The operating range can conveniently be adjusted by changing the feedback resistor, which is external in some types. FBAs work down to zero frequency, but the servo loop becomes ineffective at some high frequency (typically between 100 and 1000 Hz), above which the arrangement acts like an ordinary inertial displacement sensor. FBAs are therefore low-pass filters for ground acceleration and high-pass filters for ground displacement.

4.3 Velocity Broadband Seismometers

For broadband seismic recording with high sensitivity, an output signal proportional to ground acceleration is unfavorable. At high frequencies, sensitive accelerometers are easily saturated by traffic noise or impulsive disturbances. At low frequencies, a system with a response that is flat to acceleration generates a voltage at the output as soon as the suspension is not completely balanced. Such a system would easily be saturated by the offset voltage resulting from thermal drift or tilt. What we need is a bandpass response in terms of acceleration, or equivalently a high-pass response in terms of ground velocity, like that of a normal electromagnetic seismometer but with a lower corner frequency. Essentially the same considerations are expressed in Section 5.5 as the rule that the response of a broadband seismometer should be approximately inverse to the spectral distribution of the noise.

The desired velocity broadband (VBB) response is obtained from the FBA circuit by adding paths for differential feedback and integral feedback (Fig. 7). The capacitor C is chosen so large that the differential feedback dominates throughout the desired passband. While the feedback current is still proportional to ground acceleration as before, the voltage across the capacitor C is a time integral of the current, and thus proportional to ground velocity. This voltage serves as the output signal. The factor of proportionality—the apparent generator constant of the feedback seismometer—is

$$V = \frac{M}{\sigma C} \quad (15)$$

FIGURE 7 VBB feedback circuit.

Again the response is essentially determined by three passive components. Although a capacitor with a solid dielectric is not quite as ideal a component as a good resistor, the response is still linear and very stable.

The output signal of the integrator is normally accessible at the “mass position” output. It does not indicate the actual position of the mass but indicates where the mass would go if the feedback were switched off. “Centering” the mass of a feedback seismometer (by adjusting its weight or the spring force) has the effect of discharging the integrator so that its full operating range is available for the seismic signal. The mass-position output is not normally used for seismic recording but is useful as a state-of-health diagnostic, and is used in some calibration procedures.

The relative strength of the integral feedback increases at lower frequencies, while that of the differential feedback decreases. At some frequency, the two contributions are of equal strength but opposite phase ($-\pi/2$ and $\pi/2$, respectively). This is the lower corner frequency of the feedback system, below which the response rolls off with the second derivative of ground velocity. The differential and the integral parts of the feedback cancel at the corner frequency, but the proportional feedback remains and damps the resonance that would otherwise occur. As a result, the feedback system behaves like a conventional electromagnetic seismometer and can be described by the usual three parameters: free period, damping, and generator constant. In fact most of the presently used electronic broadband seismometers follow the simple theoretical response of electromagnetic seismometers more closely than these ever did.

At some high frequency, the loop gain falls below unity. This is the upper corner frequency of the feedback system, which marks the transition between a response flat to velocity and one flat to displacement. A well-defined and nearly ideal behavior of the seismometer as at the lower corner frequency should not be expected there, both because the feedback becomes ineffective and because most suspensions have parasitic resonances slightly above the electrical corner frequency (otherwise they could have been designed for a larger bandwidth). However, the detailed response at the high-frequency corner rarely matters since the upper corner frequency is usually outside the passband of the recorder. Its effect on the transfer function can in most cases be modeled

as a small, constant delay (a few milliseconds) over the whole VBB passband.

4.4 The Response of Force-Balance Seismometers

For completeness we give here a slightly simplified formula for the complex frequency response of a broadband force-balance seismometer. The simplification consists in ignoring the mechanical restoring force and damping, which can be absorbed into the electrical parameters, and the impedance of the feedback coil, which can be made small. When X is the Fourier amplitude of the ground displacement and E that of the output voltage, then the response to ground velocity is

$$\frac{E}{j\omega X} = \frac{\omega^2 M / \sigma C}{-j\omega^3 M / \alpha \sigma C - \omega^2 + j\omega / R_1 C + 1 / \tau R_2 C} \quad (16)$$

The leading term in the denominator disappears when the responsivity α of the displacement transducer is large. What remains is an ordinary high-pass response with a corner frequency $1/\sqrt{\tau R_2 C}$, damping $\sqrt{\tau R_2 / 4CR_1^2}$, and generator constant $M/\sigma C$. The response is thus identical to that of a conventional electrodynamic seismometer [Eq. (11)]. The realization of a “very-broadband” type of seismometer, with a free period of 100 sec or more, depends on the ability to build an integrator with a long time-constant τ and low electronic noise (Wielandt and Steim, 1986). At high frequencies, the bandwidth is limited by the finite responsivity α of the displacement transducer. The loop gain falls below unity and the velocity response rolls off with $1/j\omega$ at frequencies above $\alpha \sigma C / 2\pi M$; the response is then flat to displacement. The resistance and inductance of the feedback coil, phase delays in the electronic circuit, and parasitic resonances in the suspension make the feedback loop unstable for large α and thus set a limit to the upper corner frequency of the response.

The reader is referred to publications by Usher *et al.* (1978), Wielandt (1983), and Wielandt *et al.* (1982, 1986) for a deeper discussion.

5. Design Criteria for Broadband Seismographs

5.1 The Concept of Very-Broadband Seismometry

Earthquakes and other seismic sources radiate signals in a large range of frequencies and amplitudes. In a logarithmic scale, the seismic frequency band is much broader than that of audible tones. Only a limited range of these signals can be visibly displayed at a time. So any seismograph recording on paper or film has to act as a filter and suppress most of the available

information. Quite a number of analog seismographs with different characteristics had to be operated in parallel in order to preserve a reasonable choice of signals. Digital technology now permits the recording of all useful seismic signals on the same medium in a single data stream. Such a system is called a very-broadband (VBB) seismograph. It must meet the following requirements (IRIS, 1985; Wielandt and Steim, 1986):

1. The system must have a sensitivity sufficient to resolve signals at the level of minimum ground noise at all frequencies of interest.
2. Its operating range must be large enough to record the largest earthquakes at regional to teleseismic distances.
3. The largest ground noise, natural or artificial, that is likely to occur in any part of the spectrum must not interfere with the resolution of small signals at other frequencies.

A few explanations are required. A signal is said to be *resolved* when it is present in the seismic record and not masked by instrumental noise. The minimum ground noise is different at each station, but for a uniform system intended for global deployment the instrumental sensitivity must be designed for the global minimum. The present standard is the New Low Noise Model (NLNM) compiled by Peterson (1993). A simple computer program converting noise data into different units and comparing them to the NLNM is available from the author's FTP site (see Section 11). The *operating range* is the maximum signal amplitude that can pass through the system without serious distortion.

The above requirements can be visualized in a doubly-logarithmic diagram like Figure 8, where the levels of ground noise and earthquake signals are expressed in common units, here as average peak values in 1/3 octave or rms values in 1/6 decade (these two measures happen to coincide within a few per cent). In other contexts, noise levels are normally expressed as power spectral densities, which cannot be compared directly with the amplitudes of transient signals. The amplitude ratio between the instrumental noise and the clipping level of a sensor or a recorder is called its *dynamic range*. It is usually expressed in decibels and depends on frequency and on the bandwidth in which it is measured; without this information its specification is meaningless. The reference bandwidth should be chosen with a view to the narrowest bandwidth useful for a waveform plot at each frequency. *Absolute dynamic range* is short for a specification of the dynamic range in absolute signal levels.

5.2 The Sensitivity of Force-Balance Seismometers

The spectral distribution of minimum ground noise is such that noise is difficult to resolve at both the short-period and long-period ends of the seismic band. At short periods, the ground displacements in the NLNM (Fig. 8) are very

FIGURE 8 A representation of the USGS New Low Noise Model in comparison with the self-noise and operating range of the STS1 very-broadband seismometer. Signal levels are expressed as decibels relative to 1 m sec^{-2} and may be understood as rms values in a bandwidth of 1/6 decade or average peak values in a bandwidth of 1/3 octave. At periods longer than 100 sec, the NLNM is mainly based on STS1 data. Its coincidence with the instrumental noise beyond 200 sec suggests that the STS1 seismometer may not resolve ground noise at the quietest sites (Peterson 1993).

small: 6 pm average peak in a bandwidth of 1/3 octave at 5 Hz, 0.4 pm at 30 Hz. Capacitive displacement transducers (Blumlein bridges) used in VBB seismometers typically resolve between 0.1 and 1 pm at these frequencies. The resolution cannot easily be improved without increasing the undesired effects of power consumption, heat production, electrostatic forces, and viscous (air) damping in the displacement transducer.

At long periods, the seismic noise is relatively large in terms of displacement, but the acceleration is small. Around a period of 300 sec the acceleration associated with the minimum noise is about 15 pm sec^{-1} ($1.5 \times 10^{-12} g$) in 1/3 octave. The relationship $\Delta g = \omega_0^2 \Delta z$ [Eq. (3) with Δg written for the ground acceleration $\ddot{x}$] tells us then that we need a displacement resolution of 0.1 pm when the pendulum has a free period of 0.5 sec, 10 pm at a free period of 5 sec, and 350 pm at 30 sec (the numbers are estimates for the CMG3, STS2, and STS1 seismometers, respectively). The difficulty of building a sensitive VBB seismometer with a mechanical free period substantially shorter than 1 sec is obvious.

A final limit to the sensitivity at long periods is set by the Brownian (thermal) motion of the seismic mass. Air molecules hitting the pendulum not only damp its motion but also exert a force whose spectral noise power density N is given by the same well-known formula that quantifies the voltage noise of a resistor:

$$N = 4kTR \quad (17)$$

where R is the viscous friction experienced by the seismic mass, k is the Boltzmann constant, and T is the absolute temperature.

In a typical force-balance seismometer, damping is mainly caused by the air gap of the capacitive displacement transducer. Even with a favorable capacitor geometry and with ventilation holes in the plates, thermal noise is likely to mask the minimum long-period ground noise when the seismic mass is reduced to some 10 g or less. The problem can in principle be solved by evacuating the sensor, but it would be very difficult to maintain a sufficiently high vacuum in a sensor of conventional design.

While failure to meet the basic criteria must spoil the ability to resolve minimum noise, their observation is no guarantee for a sensor to achieve the desired resolution. Additional noise may result from various mechanical, electrical, magnetic, thermal and even chemical effects, and it is difficult to predict which ones will infest a specific design.

5.3 The Operating Range of Force-Balance Seismometers

The electric operating range of a well-designed seismometer is, at least in its passband, limited by clipping at the output, at a signal level slightly below the internal supply voltage. The seismic operating range is the electrical range divided by the amplitude response, and thus in general is frequency-dependent. Clipped waveforms can normally be recognized when the signal has been recorded with adequate bandwidth. However, when clipping occurs in earlier stages of the circuit or in the feedback loop, or when the signal is low-pass filtered in the recorder, clipping may go unnoticed and the record may look quite normal even if it is severely distorted; an example is presented in Wielandt (1983).

The operating range at very low frequencies requires a separate consideration. Due to the presence of an integrator in the feedback loop, the condition that clipping should occur only at the output cannot be maintained at very low frequencies. The operating range is then limited by saturation of the integrator. Since the integrator also generates noise, it determines the dynamic range of the whole system at long periods. This has direct consequences for the ranges of drift and tilt in which force-balance seismometers can be operated. We give an order-of-magnitude estimate: The integrator may have a noise level of $0.1 \mu\text{V rms}$ (in an appropriate bandwidth) and a saturation level of $\pm 10\text{ V}$; the sensor may have been designed to resolve $10^{-12} g$ rms. Then the integrator will be saturated by static accelerations of $\pm 10^{-4} g$. A vertical sensor whose suspension has a temperature coefficient of 10^{-5} per Kelvin could be operated with this feedback system in a temperature range of $\pm 10\text{ K}$; a horizontal sensor would have to be leveled to within 0.1 mm m^{-1} .

The designer of a force-balance seismometer has a considerable freedom in the choice of the responsivity and thus of the seismic operating range. The dynamic range of sensors and recorders is limited, however, so a decision must be made whether the operating range or the self-noise of a system should be specified in the first place. Recording systems for strong motion usually have a certain level of ground acceleration specified as the operating range. General-purpose seismographs are normally designed to resolve ground noise; their operating range is then made as large, and their gain as small, as this requirement permits.

5.4 Digitizer Noise

An ideal digitizer rounds the samples of the input signal to integer multiples of a quantum q (one count), which can be expressed as an equivalent step of the input voltage. The sequence of rounding errors constitutes the quantization noise. Under certain conditions it is white and has a constant total power of $q^2/12$ in the band from zero to the Nyquist frequency (half the sampling frequency). Its spectral density therefore depends on the sampling rate, and can be reduced by oversampling and subsequent bandwidth reduction. However, digitizers also exhibit ordinary electronic noise both of the white and the $1/f$ variety, which cannot be reduced by oversampling. Filters for bandwidth reduction must have some gain or use floating-point arithmetic in order to avoid additional quantization errors. Nonlinear distortions in modern 24-bit digitizers are normally so small that they can safely be ignored.

5.5 Matching Sensors and Recorders

The clipping level of a seismic recording system—sensor plus recorder—is the minimum of the clipping levels of the components. On the other hand, the supposedly uncorrelated noise

levels of the components add up like orthogonal vectors. The overall dynamic range of the system is therefore always smaller than that of each subsystem. (To be comparable, all signal levels must be referred to the same point in the circuit, or expressed as ground motion.) To make best use of the absolute dynamic ranges of the components, the smallest one must be contained in all others. When the dynamic ranges of the sensor and the recorder are of similar magnitude, as is the case with modern broadband sensors and 24-bit digitizers, this condition determines the optimum gain of the sensor within narrow limits.

Similar considerations apply to the seismic input signals. The Earth may in this context be considered as another signal-transmitting system with its own noise and operating range. For a system to resolve ground noise, the sensor must not only have a self-noise below that noise but must also put out the combined ground and sensor noise as an electric signal above the digitizer noise. The necessary gain margin has occasionally been a matter of controversial discussion. A factor of 2 should normally be sufficient; the digitizer noise then increases the noise amplitude by only 12%. Using a larger gain margin would unnecessarily reduce the seismic operating range. A small gain margin does not preclude the extraction of coherent signals from incoherent noise by bandwidth reduction, stacking, or beamforming. When the system resolves incoherent ground noise, it also resolves all coherent signals that can theoretically be extracted from it.

If the digitizer noise were white, the optimum response of the sensor would be inverse to the spectral distribution of the minimum noise. The latter is, however, too complicated to be modeled in a practical sensor. Experience has shown that a response flat to velocity, from short periods to a long-period corner of 100 sec or more, is sufficiently close to the optimum. A more detailed discussion of this topic is found in Wielandt and Steim (1986).

5.6 Scaling Down Seismometers

Seismometers should be as small as possible for easier transportation, installation, and shielding, and because internal air convection (which causes noise) is more easily suppressed in a smaller volume. It is therefore interesting to see what happens if a given design is scaled down by a factor of γ . A simple calculation shows that strict scaling is not possible for vertical sensors that are in equilibrium with terrestrial gravity. The mass, the spring force, and the spring stiffness scale with different powers of γ (3, 2, and 1, respectively). The spring would be too strong in a downscaled version and must be made slightly thinner than to scale; nevertheless, it remains too stiff. The mechanical sensitivity to long-period accelerations is thereby reduced by a factor of γ , and the period becomes shorter by a factor $\sqrt{\gamma}$ as for a simple pendulum. On the other hand, the resolution of the displacement transducer will suffer from the smaller size of the capacitor plates. Air damping in the

displacement transducer is also undesirably increased (see Section 5.2 and Jones and Richards, 1973). It is, by the way, unlikely that one would want to reduce the gap between the plates because, if this were practical, one would have done it in the first place. The signal-to-noise ratio at long periods will therefore go down at least with the square of the scaling factor. Undesired forces causing nonlinearity or noise will in general scale with a smaller power of γ than the mass, and thus become relatively larger. Finally, Brownian noise will come up when the mass is too small, as mentioned above. So it appears that miniature seismometers require different designs and are unlikely to reach the sensitivity of presently available VBB seismometers in the near future. There is no doubt, however, that existing designs could be scaled down by a factor of 2 or so, which would make the instruments very handy.

6. Site Selection, Installation and Shielding

6.1 Site Selection

Site selection for a permanent seismic station is always a compromise between two conflicting requirements: infrastructure and low seismic noise. The noise level depends on the geological situation and on the proximity of sources, some of which are usually associated with the infrastructure. A seismograph installed on solid basement rock can be expected to be fairly insensitive to local disturbances, while one sitting on a thick layer of soft sediments will be noisy even in the absence of identifiable sources. As a rule, the distance from potential sources such as houses and roads should be large compared to the thickness of the sediment layer. Broadband seismographs can be successfully operated in major cities when the geology is favorable; in unfavorable situations, such as in sedimentary basins, only deep mines and boreholes may offer acceptable noise levels.

Seismic noise has many different causes. Short-period noise is at most sites predominantly man-made and somewhat larger in the horizontal components than in the vertical. At intermediate periods (2–20 sec), marine microseisms dominate with similar amplitudes in the horizontal and vertical directions. At long periods, horizontal noise may be larger than vertical noise by a factor up to 300, the factor increasing with period. This is mainly due to tilt, which couples gravity into the horizontal components but not into the vertical. Tilt may be caused by traffic, wind, or the barometric pressure. Large tilt noise is sometimes observed on concrete floors when an unventilated cavity exists underneath; the floor then acts like a membrane. Such noise can be identified by its linear polarization and its correlation with the barometric pressure. The sound of a hammer stroke tells a lot about the solidity of a floor. Even on an apparently solid foundation, the long-period noise often correlates with the barometric pressure (Beauduin

et al., 1996). If the situation cannot be remedied otherwise, the barometric pressure should be recorded with the seismic signal and used for a correction. For very-broadband seismographic stations, barometric recording is generally recommended.

Besides ground noise, environmental conditions must be considered. Although seismometers can and must be shielded against these, an aggressive atmosphere may cause corrosion, short-term variations of temperature may induce noise, and seasonal variations of temperature may exceed the drift specifications. As a precaution, cellars and vaults should be checked for signs of occasional flooding.

6.2 Seismometer Installation

We briefly describe the installation of a portable broadband seismometer inside a building, vault, or cave. The first act is to mark the orientation of the sensor on the floor. This is best done with a geodetic gyroscope, but a magnetic compass will do in most cases. The magnetic declination must be taken into account. Since a compass may be deflected inside a building, the direction should be taken outside and transferred to the site of installation. A laser pointer may be useful for this purpose. When the declination is unknown or unpredictable (such as in high latitudes or volcanic areas), the orientation should be determined with a sun compass.

To isolate the seismometer from stray currents, small glass or Perspex plates are cemented to the ground under its feet. Then the seismometer is installed, tested, and wrapped with a thick layer of thermally insulating material. The type of material seems not to matter very much; alternate layers of fibrous material and heat-reflecting blankets are probably most effective. The edges of the blankets should be taped to the floor around the seismometer. Electronic seismometers produce heat and may induce convection in any open space inside the insulation; it is therefore important that the insulation has no gap and fits the seismometer tightly. Another method of insulation is to surround the seismometer with a large box that is then filled with fine styrofoam seeds. For a permanent installation under unfavorable environmental conditions, the seismometer must be enclosed in a hermetic container. A problem with such containers (as with all seismometer housings) is that they cause tilt noise when they are deformed by the barometric pressure. Essentially three precautions are possible: the baseplate is carefully cemented to the floor, or it is made so massive that its deformation is negligible, or a “warp-free” design is used as described by Holcomb and Hutt (1992) for the STS1 seismometers. Some desiccant should be placed inside any hermetic container, even into the vacuum bell of STS1 seismometers.

Guidelines for installing broadband seismic instrumentation are offered at the web site of the Seismological Lab at Berkeley (Uhrhammer and Karavas, 1997). Detailed instructions for the design of seismic vaults are given by Trnkoczy (1998).

6.3 Installation of Strong-Motion Instruments

Although strong-motion instruments are sometimes installed side by side with broadband instruments, their site is normally selected on different criteria. For purposes of seismic engineering, strong-motion records may be desired where one would not normally install a seismic station—for example, in power stations or high-rise buildings. The instruments must be cemented or bolted to the structure; in regions of high epicentral intensity, they should also be protected from falling debris. Other considerations apply when free-field signals are to be recorded. At high frequencies and when the soil is soft, nearby buildings and even the instrument vault itself may modify the signal. The vault should in this case be a small, rigid structure that is firmly coupled to the ground on all sides. Since strong-motion recorders are normally operated in an event-triggered mode and may not record any ground motion for long intervals of time, their state of health must be regularly checked with test signals.

6.4 Magnetic Shielding

Broadband seismometers are to some degree sensitive to magnetic fields because all thermally compensated spring materials are slightly magnetic. This may become noticeable when seismometers are operated in industrial areas or in the vicinity of dc-powered railway lines. When long-period noise is found to follow a regular timetable, magnetic interferences should be suspected. Shields can be manufactured from permalloy metal but are expensive and of limited efficiency. An active compensation is often preferable. It may consist of a three-component fluxgate magnetometer that senses the field near the seismometer, an electronic driver circuit in which the signal is integrated with a short time constant (a few milliseconds), and a three-component set of Helmholtz coils that compensate changes of the magnetic field. The permanent geomagnetic field should not be compensated; the resulting offsets of the fluxgate outputs can be compensated with a permanent magnet or electrically.

7. Deconvolution

7.1 General Deconvolution

It is often necessary to restore the original ground motion from a seismogram. For this purpose, the seismogram must be filtered with the inverse response of the seismograph, a process known as deconvolution. It is rarely carried out in its exact mathematical form because the signal-to-noise ratio deteriorates outside the passband of the seismograph, and the deconvolution must be limited to a passband where the signal-to-noise ratio is still acceptable. Generally speaking, the ground motion is not entirely determined by the seismic

record, and its reconstruction is a geophysical inverse problem whose solution must be constrained by a priori information. Similar considerations apply to the case when records from seismographs with different responses must be homogenized. The PREPROC software package (Plesinger *et al.*, 1996) contains different routines for a bandlimited deconvolution and its manual offers a concise introduction to the problem.

A deconvolution can be realized in the frequency or the time domains. The frequency domain is convenient for the construction of approximate inverses with a view to the frequency-dependent signal-to-noise ratio of the data. Causal and acausal solutions are available; waveforms may be better preserved with an acausal inverse, but the resulting precursory signals may give rise to misinterpretation. A division-by-zero problem exists in the low-frequency limit and prevents the construction of an exact inverse. In the time domain, both approximate and quasi-exact inverses can conveniently be realized with recursive (IIR) filters. They are always causal. Short time-series can often be deconvolved with a quasi-exact inverse; no division-by-zero problem is encountered but a quadratic or cubic trend may be generated, which can be removed afterward by polynomial fitting.

7.2 Removing the Noncausal Response of Digital Recorders

The response of digital recorders is normally determined by digital, finite impulse response (FIR) filters that decimate the oversampled data stream. The transfer functions of such filters are transcendental functions, and it is neither correct nor practical to specify them by poles and zeros in frequency domain as if they were rational functions.

Essentially two types of FIR filters are used. Most recorders have zero-phase filters that do not introduce phase shifts; their response can simply be ignored in the overall response of a digital seismograph, except for their limiting the bandwidth. Zero-phase filters are, however, noncausal and can produce spurious precursors of seismic arrivals. This is a problem when first arrivals must be picked, in which case it is preferable to have minimum-phase decimation filters. These, on the other hand, introduce frequency-dependent delays that must be removed from the data in other applications. It is possible to convert a zero-phase filtration into a minimum-phase filtration, and vice versa, by applying a suitable all-pass filter to the data (Scherbaum, 1996). The problem is treated elsewhere in this Handbook.

Problems with acausal zero-phase filters can also be avoided by filtering the data with a causal filter of smaller bandwidth such as a Butterworth low-pass filter, or with the response of a classical electromagnetic seismograph. The influence of the original decimation filter then disappears and only the response of the user-specified filter must be considered.

8. Testing for Linearity and Noise

8.1 Testing for Linearity

Seismographs need not record the ground motion with extreme precision; most methods of interpretation do not depend on minor amplitude errors or waveform distortions. In one respect, however, a broadband seismograph must be precise: it must be a linear system, that is, it must conform to the principle of superposition. The sum of two input signals must produce the sum of the corresponding output signals and nothing else. Then, the presence of any number of input signals in a given frequency band will not produce an output signal in another band. This is a prerequisite for being able to record small long-period signals in the presence of strong short-period signals, or vice versa.

The electrical linearity of a seismometer is usually checked with a two-tone test (Peterson *et al.*, 1980). Two sinusoidal signals of equal amplitude and nearly equal frequency (for example, 1.00 and 1.02 Hz) are applied to the calibration input and their low-frequency (0.02 Hz) intermodulation product is observed at the output. The measurement is facilitated by the fact that the gain of a VBB seismometer at 0.02 Hz is 50 times larger than at 1 Hz, so even a small amount of distortion will be noticeable. Another way of testing linearity is to calibrate the system with the CALEX routine (see Section 9.5) using a sweep or another nearly sinusoidal signal as an input. Nonlinear distortions, if present, are visible in the residual signal provided that the transfer function has been modeled correctly so that the linear distortions (errors in amplitude and phase) are small. Expressing the result in meaningful numbers is another problem. Linearity is not a simple concept in a system with a frequency-dependent response; the test conditions must be precisely defined. Referring the result to the input (acceleration) in place of the output (velocity) may have a large cosmetic effect.

Good electrical linearity unfortunately does not ensure that the system is equally linear for seismic signals. Mechanical forces in the sensor and nonlinear behavior of the force transducer may differ between an electrical and a mechanical experiment. Moreover, a sensor might respond in a nonlinear way to transverse accelerations that cannot be excited electrically. Unfortunately, it is nearly impossible to observe the mechanical nonlinearity of a force-balance seismometer on a shake table. Such experiments invariably end up as tests of the table with the seismometer as the reference. Even a small tilt component in the motion of the table can produce stronger spurious signals than a suspected nonlinearity of the sensor. A seismometer may, however, be considered as sufficiently linear when it produces undisturbed long-period records during local earthquakes (Wielandt and Streckeisen, 1982).

8.2 Measuring Instrumental Noise

Force-balance sensors cannot be tested for noise with the mass locked, so the instrumental noise can only be observed

in the presence of seismic noise. This may nevertheless be useful as a first check; a broadband seismograph that resolves tides or free oscillations of the Earth cannot be too bad at long periods. For a quantitative assessment of instrumental noise, however, the two contributions must be separated from each other. The usual procedure is to perform a frequency-domain analysis of the coherency between the output signals of two seismometers, and to assume that coherent noise is seismic and incoherent noise is instrumental. This is, however, questionable because the two instruments may respond coherently to environmental disturbances such as caused by barometric pressure, temperature, the supply voltage, magnetic fields, vibrations, or electromagnetic waves. Nonlinear behavior (intermodulation) may produce coherent but spurious long-period signals. The reference instrument should therefore be one whose (relative) immunity to intermodulation and environmental conditions is known; otherwise two instruments of a different type or at least in a different setup and with different power supplies should be used, hoping that they will not respond to disturbances in a coherent manner.

The analysis for coherency is somewhat tricky in detail. When the transfer functions of both instruments are known, it is in fact theoretically possible to measure the seismic signal and the instrumental noise of each instrument separately as a function of frequency. However, the transfer functions must be known with great precision for this purpose. Alternatively, one may assume that the reference instrument is noise-free; in this case the noise and the transfer function of the other instrument can be determined. Long time-series are required for reliable results: the analysis is made in a set of narrow frequency bands, and the length of the record multiplied with the smallest bandwidth must be a large number. We offer a computer program UNICROSP for the analysis.

8.3 Transient Disturbances

Most new seismometers produce spontaneous transient disturbances, quasi miniature earthquakes caused by stresses in the mechanical components. Although they do not necessarily originate in the spring, their waveform at the output seems to indicate a sudden and permanent (steplike) change in the spring force. Long-period seismic records are sometimes severely degraded by such disturbances. The transients often die out within some months or years; if not, and especially when their frequency increases, corrosion must be suspected. Manufacturers try to mitigate the problem with a low-stress design and by aging the components or the finished seismometer (by extended storage, vibration, or alternate heating and cooling cycles). It is sometimes possible to virtually eliminate transient disturbances by hitting the pier around the seismometer with a hammer, a procedure that is recommended in each new installation.

9. Calibration

9.1 Electrical and Mechanical Calibration

The calibration of a seismograph establishes knowledge of the relationship between its input (the ground motion) and its output (an electric signal), and is a prerequisite for a reconstruction of the ground motion. Since precisely known ground motions are difficult to generate, one makes use of the equivalence between ground accelerations and external forces on the seismic mass [Eq. (2)] and calibrates seismometers with an electromagnetic force generated in a calibration coil. If the factor of proportionality between the current in the coil and the equivalent ground acceleration is known, then the calibration is a purely electrical measurement. Otherwise, the missing parameter—either the transducer constant of the calibration coil, or the responsivity of the sensor itself—must be determined from a mechanical experiment in which the seismometer is subjected to a known mechanical motion or a known tilt. This is called an absolute calibration. Since it is difficult to generate precise mechanical calibration signals over a large bandwidth, one does normally not attempt to determine the complete transfer function in this way.

The present section is mainly concerned with the electrical calibration, although the same methods may also be used for the mechanical calibration on a shake table. Specific procedures for mechanical calibration without a shake table are presented in Section 10.

9.2 General Conditions

Calibration experiments are disturbed by seismic noise and tilt, and should therefore be carried out in a basement room. However, the large operating range of modern seismometers permits calibration with relatively large signal amplitudes, making background noise less of a problem than one might expect. Thermal drift is more serious because it interferes with the long-period response of broadband seismometers. These should be protected from draft and allowed sufficient time to reach thermal equilibrium. Visual and digital recording in parallel is recommended. Recorders must themselves be absolutely calibrated before they can serve to calibrate seismometers. The input impedance of recorders as well as the source impedance of sensors should be measured so that a correction can be applied for the loss of signal in the source impedance.

9.3 Calibration of Geophones

Simple electrodynamic seismometers (geophones) have no calibration coil. The calibration current must then be sent through the signal coil. There it produces an ohmic voltage in addition to the output signal generated by the motion of the mass. The simplest way of circumventing this difficulty is to excite the geophone by interrupting a constant current through

FIGURE 9 Half-bridge circuit for calibrating geophones.

the coil, and to evaluate the resulting transient response either graphically or with any suitable program for system identification (Rodgers *et al.*, 1995). The method will also supply the generator constant when the size of the mass is known and its motion is linear. When other calibration signals are used, the undesired voltage can be compensated in a bridge circuit (Willmore, 1959); the bridge is zeroed with the geophone clamped or inverted. However, when both the calibration current and the output voltage are digitally recorded, it is more convenient to use only a half-bridge (Fig. 9) and to compensate the ohmic voltage numerically. The program CALEX described below has provisions to do this automatically.

Eigenfrequency and damping of geophones (and of most other seismometers) can be determined graphically with a set of standard resonance curves on doubly-logarithmic paper. The measured amplitude ratios are plotted on the same type of paper and overlaid with the standard curves (Fig. 10). The desired quantities can be read directly. The method is simple but not very precise.

Geophones whose seismic mass moves along a straight line require no mechanical calibration when the size of the mass is known. The electromagnetic part of the numerical damping is inversely proportional to the total damping resistance [Eq. (13)]; the factor of proportionality is $\sigma^2/2M\omega_0$, so the generator constant σ can be calculated from electrical calibrations with different resistive loads.

9.4 Calibration with Sine Waves

With a sinusoidal input, the output of a linear system is also sinusoidal, and the ratio of the two signal amplitudes is the amplitude response (the modulus of the complex frequency response). An experiment with sine waves therefore permits an immediate check of the response, without any a priori knowledge of its mathematical form and without waveform modeling; this is often the first step in the identification of an unknown system. A computer program would, however, be required for converting discrete values of the response function into a parametric representation; a calibration with arbitrary signals as described later is more straightforward for this purpose.

When only analog equipment is available, the calibration coil or the shake table may be driven with a sinusoidal test signal and the input and output signals recorded with a chart recorder or an X-Y recorder. On the latter, the signals should

FIGURE 10 Normalized resonance curves.

be plotted as a Lissajous ellipse from which both the amplitude ratio and the phase can be read with good accuracy. The signal period should be measured with a counter or a stop watch because the frequency scale of sine wave generators is often inaccurate.

The accuracy of the graphic evaluation depends on the purity of the sine wave. A better accuracy can of course be obtained with a numerical analysis of digitally recorded data. By fitting sine waves to the signals, amplitudes and phases can be extracted for just one precisely known frequency at a time; distortions of the input signal then do not matter. For best results, the frequency should be fitted as well, the fit should be computed for an integer number of cycles, and offsets should be removed from the data. A FORTRAN program "SINFIT" is offered for this purpose (Section 11).

9.5 Calibration with Arbitrary Signals

The purpose of calibration is in most cases to obtain the parameters of an analytic representation of the transfer function. Assuming that its mathematical form is known, the task is to determine its parameters from an experiment in which both the input and the output signals are recorded. This is a classical inverse problem that can be solved with standard least-squares methods.

The general concept is as follows. A computer algorithm is implemented that represents the seismometer as a filter and permits the computation of its response to an arbitrary input. An inversion algorithm is programmed around the filter algorithm in order to find best-fitting parameters for a given pair of input and output signals. A calibration experiment is then made with a test signal for which the response of the system is sensitive to the unknown parameters but which is

otherwise arbitrary. When the system is linear, parameters determined from one test signal will also predict the response to any other signal.

The approximation of a rational transfer function with a discrete filtering algorithm is not trivial (see Section 3.4). For the program CALEX that accompanies this article, we have chosen an impulse-invariant recursive filter after Schuessler (1981). The method formally requires that the seismometer has a negligible response at frequencies outside the Nyquist bandwidth of the recorder, a condition that is severely violated by most digital seismographs; but this problem can be circumvented with an additional sharp low-pass filtration within the program. Figure 11 shows signals from a typical calibration experiment with CALEX. The test signal is a sweep, which permits the residual error to be visualized as a function of frequency even when the whole algorithm works in the time domain. When the transfer function has been correctly parametrized and the inversion has converged, then the residual error consists mainly of noise, drift, and nonlinear distortions. At a signal level of about one-third of the operating range, typical residuals are 0.03% to 0.05% rms for force-balance seismometers and $\geq 1\%$ for passive electrodynamic sensors.

With an appropriate choice of the test signal, other methods such as calibration with sine waves, step functions, random noise, or random telegraph signals can be duplicated and compared to each other. An advantage of the CALEX algorithm is that it makes no use of special properties of the test signal, such as being sinusoidal, periodic, steplike, or random. Therefore, test signals can be short (a few times the free period of the seismometer), and they can be generated with the most primitive means, even by hand. A breakout box or a special cable may, however, be required for feeding the calibration signal into the digital recorder. Alternative routines for

FIGURE 11 Electrical calibration of a STS2 seismometer with CALEX. Traces from top to bottom: input signal (a sweep with a total duration of 10 min); observed output signal; modelled output signal; residual. The rms residual is 0.05% of the rms output.

seismograph calibration are contained in the free PREPROC software package (Plešinger *et al.*, 1996; see Section 11).

then adjusted so that the signal appears only at the desired output of the seismometer.

9.6 Calibration of Triaxial Seismometers

In a triaxial seismometer such as the STS2 (Fig. 5), transfer functions in a strict sense can only be attributed to the individual U , V , W sensors, not to the X , Y , Z outputs. Formally, the response of a triaxial seismometer to arbitrary ground motions is described by a nearly diagonal 3×3 matrix of transfer functions relating the X , Y , Z output signals to the X , Y , Z ground motions. (This is also true for conventional three-component sets if they are not perfectly aligned; only the composition of the matrix is slightly different.) If the U , V , W sensors are reasonably well matched, the effective transfer functions of the X , Y , Z channels have the traditional form and their parameters are weighted averages of those of the U , V , W sensors. The X , Y , Z outputs can therefore be calibrated as usual. For the simulation of horizontal and vertical ground accelerations via the calibration coils, each sensor must receive an appropriate portion of the calibration current. For the vertical component this is approximately accomplished by connecting the three calibration coils in parallel. For the horizontal components and also for a more precise excitation of the vertical, the calibration current must be split into three individually adjustable and invertible components. These are

10. Procedures for the Mechanical Calibration

10.1 Calibration on a Shake Table

Using a shake table is the most direct way of obtaining an absolute calibration. In practice, however, precision is usually poor outside a frequency band roughly from 0.5 to 5 Hz. At higher frequencies, a shake table loaded with a broadband seismometer may develop parasitic resonances, and inertial forces may cause undesired motions of the table. At low frequencies, the maximum displacement and thus the signal-to-noise ratio may be insufficient, and the motion may be nonuniform due to friction or roughness in the bearings. Still worse, most shake tables do not produce a purely translational motion but also produce some tilt. This has two undesired side-effects: the angular acceleration may be sensed by the seismometer, and gravity may be coupled into the seismic signal (see Section 2.4). The latter effect can be catastrophic for the horizontal components at long periods since the error increases with the square of the signal period. One might think that a tilt of $10 \mu\text{rad}$ per mm of linear motion should

not matter; however such a tilt will, at a period of 30 sec, induce seismic signals twice as large as those originating from the linear motion. At a period of 1 sec, the same tilt would be negligible. Long-period measurements on a shake table, if possible at all, require extreme care.

Although all calibration methods mentioned in the previous section are applicable on a shake table, the preferred method would be to record both the motion of the table (as measured with a displacement transducer) and the output signal of the seismometer, and to analyze these signals with CALEX. Depending on the definition of active and passive parameters, only the absolute gain (responsivity, generator constant) or any number of additional parameters of the transfer function may be determined.

10.2 Calibration by Stepwise Motion

The movable tables of machine tools like lathes and milling machines, and of mechanical balances, can replace a shake table for the absolute calibration of seismometers. The idea is to place the seismometer on the table, let it come to equilibrium, then move the table manually by a known amount and let it rest again. The total motion can then be calculated from the seismic signal and compared to the actual mechanical displacement. Since the calculation involves triple integrations, offset and drift must be carefully removed from the seismic trace. The main contribution to drift in the apparent horizontal "ground" velocity comes from tilt associated with the motion of the table. With the method subsequently described, it is possible to separate the contributions of displacement and tilt from each other so that the displacement can be reconstructed with good accuracy. This method of calibration is most convenient because it uses only normal workshop equipment; the inherent precision of machine tools and the use of relatively large displacements eliminate the problem of measuring small displacements. A FORTRAN program named DISPCAL is available for the evaluation.

The precision of the method depends on minimizing errors from two sources:

1. The numerical restoration of ground displacement from the seismic signal (a process of inverse filtration) is noncritical for broadband seismometers but requires a precise knowledge of the transfer function of short-period seismometers. Instruments with unstable parameters must be electrically calibrated while installed on the test table. However, when the response is known, the restitution of absolute ground motion is no problem even for a geophone with a free period of 0.1 sec.
2. The effect of tilt can only be removed from the displacement signal when the motion is sudden and short. The tilt is unknown during the motion, and is integrated twice in the calculation of the displacement. So the longer the interval of motion, the more effect the

unknown tilt will have on the displacement signal. Practically, the motion may last about one second on a manually operated machine tool, and about a quarter-second on a mechanical balance. It may be repeated at intervals of a few seconds.

Static tilt before and after the motion produces linear trends in the velocity that are easily removed before the integration. The effect of tilt during the motion can, however, only approximately be removed by interpolating the trends before and after the motion. The computational evaluation consists in the following major steps (Fig. 12):

1. The trace is deconvolved with the velocity transfer function of the seismometer.
2. The trace is piecewise detrended so that it is close to zero in the motion-free intervals; interpolated trends are removed from the intervals of motion.
3. The trace is integrated.
4. The displacement steps are measured and compared to the actual motion.

In principle, a single steplike displacement is all that is needed. However, the experiment takes so little time that it is convenient to produce a dozen or more equal steps, average the results, and do some error statistics. On a milling machine or lathe, it is recommended to install a mechanical device that stops the motion after each full turn of the spindle. On a balance, the table is repeatedly moved from stop to stop. Its amplitude may be measured with a micrometer dial but may also be determined from the lever ratio, which in turn is obtained from the ratio of equivalent weights.

From the mutual agreement between a number of different experiments, and from the comparison with a calibration on a precise shake table, the absolute accuracy of the method is estimated to be better than 1%.

10.3 Calibration with Tilt

Accelerometers can be statically calibrated on a tilt table. Starting from a horizontal position, the fraction of gravity coupled into the sensitive axis equals the sine of the tilt angle. (A tilt table is not required for accelerometers with an operating range exceeding $\pm 1g$; these are simply turned over.) Force-balance seismometers normally have a mass-position output that is a slowly responding acceleration output. This output can, with some patience, likewise be calibrated on a tilt table; the small static tilt range of sensitive broadband seismometers may, however, be inconvenient. The transducer constant of the calibration coil is then obtained by sending a direct current through it and comparing its effect with the tilt calibration. Finally, by exciting the coil with a sine wave whose acceleration equivalent is now known, the absolute calibration of the broadband output is obtained. The method is not explained in more detail here because a simpler method exists. In any

FIGURE 12 Absolute mechanical calibration of an STS1-BB seismometer on the table of a milling machine, evaluated with DISPCAL. Traces from top to bottom: recorded BB output signal; restored and detrended velocity; restored displacement.

case, triaxial seismometers cannot be calibrated in this way because they do not have X , Y , Z mass-position signals.

The method we propose (for horizontal components only; program TILTCAL) is similar to what was described in Section 10.2, but this time we excite the seismometer with a known step of tilt and evaluate the recorded output signal for acceleration rather than displacement. This is simple because we only have to look at the drift rate of the deconvolved velocity trace before and after the step; no baseline interpolation is involved. In order to produce repeatable steps of tilt, it is useful to prepare a small lever by which the tilt table or the seismometer can quickly be tilted forward and back by a known amount. The tilt may be larger than the static operating range of the seismometer; one then has to watch the output signal and reverse the tilt before the seismometer goes to a stop.

11. Free Software

FORTRAN source code of six computer programs mentioned in the text is included on the attached Handbook CD. Both source and executable code can be downloaded from the author's FTP site (see below). These are standalone programs for calibrating and testing seismometers and for standardizing noise data; they do not form a package for general seismic processing such as SAC, SEISMIC UNIX, PITSA, or

PREPROC (see below). A README file with explanations, a set of test data, and output files are provided with each program. No graphics are included. The data files have the following format:

- A header line (text only).
- A line in the format (i10, a20, f10.x) that contains the number of samples, their format, and the sampling interval.
- Samples in ASCII.

It is suggested that users modify the input and output routines to conform with their own preferred data format. The programs are as follows:

- CALEX: Determines parameters of the transfer function of a seismometer from the response to an arbitrary input signal (which must be recorded together with the output signal). The transfer function is implemented in the time domain as an impulse-invariant recursive filter. The inversion uses the method of conjugate gradients (moderately efficient but quite failsafe).
- DISPCAL: Determines the generator constant of a horizontal or vertical seismometer from an experiment in which the seismometer is moved stepwise on the table of a machine tool or a mechanical balance.
- NOISECON: Converts noise specifications into all kind of standard and nonstandard units and compares them to the USGS New Low Noise Model (Peterson, 1993).

Interactive program available in BASIC, FORTRAN, or C, and as a DOS-Executable.

- SINFIT: Fits sine waves to a pair of sinusoidal signals and determines their frequency and the relative amplitude and phase.
- TILTCAL: Determines the generator constant of a horizontal seismometer from an experiment in which the seismometer is tilted stepwise.
- UNICROSP: Estimates seismic and instrumental noise separately from the coherency of the output signals of two seismometers.

Editor's Note

The source code of the software described in Section 11 of this chapter is placed on the attached Handbook CD, under the directory of \18Wielandt. A brief summary of the software is given in Chapter 85.18, along with other software packages available on the attached CD. Please see also Chapter 22, Analysis of Digital Earthquake Signals, by Scherbaum.

Seismic Noise on Land and on the Sea Floor

Spahr C. Webb

Lamont-Doherty Earth Observatory, Columbia University, New York, USA

1. Introduction

The study of earthquakes or the imaging of the Earth using seismic arrivals requires detecting arrivals above background noise. Differences in noise level between sites within the global seismic network can exceed 60 dB in some frequency bands (see Fig. 1), representing differences in detection threshold for seismic arrivals of four or more magnitudes. The noise level is therefore a very important criterion for choosing sites for seismic stations. The noise level at a site depends both on the quality of the installation and on the natural sources of noise close to and far from the site. This review does not attempt to

summarize the many studies of the effect of installation techniques on station quality, but does discuss the impact of borehole installation on signal-to-noise ratios for seismic arrivals both on land and under the sea. Sites poorly coupled to the ground or on poorly consolidated ground will tend to be noisy.

The perception of the seismic background depends on how one plots the noise spectra. The noise spectrum at every site is very “red” if plotted in displacement, whereas in acceleration the noise spectra have a minimum near 0.04 Hz: “a window for earthquakes” (Savino *et al.*, 1972). Most recent authors have chosen to plot noise spectra in acceleration, minimizing the apparent range. The “microseism peak” near 0.15 Hz (6 sec period) is of overwhelming importance in determining seismic noise levels. The term “microseism” is used variously to describe either any small background disturbance observed on a seismogram, or more usually this noise near 6 sec period. Short period (<1 sec) noise is mostly attributable to man-made (“cultural” sources), whereas long period (>10 sec) noise is almost always associated with natural sources: wind, waves, and water movement.

The frequency band of relevance for most seismology extends from the gravest normal mode of Earth (≈ 0.3 mHz) to an upper limit set by attenuation ranging from 20 Hz for tele-seismic events to 100 Hz or more for very local studies. This review discusses seismic noise in the band from the tides (0.02 mHz) to 50 Hz. The energetic microseism peak separates the world of seismology into its traditional short-period and long-period bands. It is usually necessary to filter data into bands either above or below this peak to clearly perceive arrivals above this noise. Until recently, seismometers were constructed as either “long-period” or “short-period” instruments with little response in the microseism band. This review continues the usual practice, and discusses the short-period and long-period bands separately.

Figure 1 shows spectra calculated using records from 75 broadband seismic stations from the global Network (Peterson, 1993). Spectral levels differ by 60 dB or more

FIGURE 1 Vertical component noise spectra from 75 stations in the global network. The envelope of these spectra defines the new high- and low-noise models (NHNM and NLNM). (Reproduced with permission from Peterson, 1993.)

FIGURE 2 (a) Broadband sea floor vertical component noise spectra from Hawaii (Webb, 1998); (b) three-component noise spectrum from offshore of central California (Sutton and Barstow, 1990) and (c) from the central North Atlantic from the seafloor (OFM) and from a sea-floor borehole (OFP) and the station SSB. (Reproduced with permission from Beauduin and Montagner, 1996.)

between the best and worst sites in most bands. The upper and lower bounds of this cloud of noise spectra have been used to derive high- and low-noise model curves, called respectively NHNM and NLNM for “new high-” or “new low-noise models.” It should be remembered that nearly all the spectra shown in this report are from preselected data. Data have been winnowed to remove sections with obvious instrument noise problems, atypical noise bursts, and seismic events. The pre-selection is a recognition that every site will be useless for seismology during some intervals. The spectra shown here are supposed to reflect obtainable noise levels during normal operation.

Although the last decade has seen a resurgence in efforts to put permanent observatories on the sea floor to extend the global arrays to these otherwise inaccessible regions, broadband seismic observations from the sea floor remain rare. Recent results suggest undersea measurements will usually be much noisier than land observations. For this reason, significant improvements in global detection thresholds will only be obtained near the sea-floor stations. The primary motivation for installing stations on the sea floor should be to improve the global ray path coverage for tomographic studies of the Earth and for regional studies of seismicity and structure.

A composite spectrum of short- and long-period vertical component data from the sea floor south of Hawaii shows noise levels considerably higher than at most continental sites at all frequencies (Fig. 2a). The long-period vertical component spectrum from another Pacific sea-floor site is similar, but the horizontal component spectra are two orders of magnitude noisier (Fig. 2b; Sutton and Barstow, 1990). The long-period vertical component spectrum (Fig. 2c) from a site in the North Atlantic is much quieter than these Pacific sites, with noise levels approaching those of good continental sites (Beauduin and Montagner, 1996). This probably reflects a real difference in noise level between these ocean basins, at least in summer. However, the horizontal component noise levels are almost as noisy as the Pacific sites.

2. Long-Period Noise and Long-Period Arrivals (<0.1 Hz)

2.1 Tides and Low-Frequency Ocean Waves (0.01 mHz–0.1 Hz)

The earth tides are below the frequencies normally used in seismology, but provide a framework for a discussion of deformation of the Earth under ocean waves and atmospheric pressure fluctuations. Tides have routinely been observed with gravimeters (long-period seismometers) and tiltmeters for decades. The apparent acceleration due to the tides has three components: (1) the large signal caused by the gravitational attraction of the Sun and Moon, (2) variations in gravity with changes in the distance to the center of the Earth from

deformation, and (3) accelerations caused directly by deformation under tidal forces. The tidal signals recorded at seismometers near coastlines or on the sea floor are further affected by ocean tidal loading. Ocean tidal loading also has three components: (1) the gravitational attraction of a changing mass of sea water adjacent to or overhead of a site, (2) variations in apparent gravity due to deformation under the time-varying load of sea water, and (3) accelerations due directly to this deformation (e.g., Lambert, 1970). The direct attraction of the sea water dominates the apparent acceleration signal at the sea floor. The ocean tidal loading signal is rarely in phase with the earth tide, and the observed earth tide at coastal stations will usually be quite different from the theoretical earth tide without ocean loading. Models of ocean tides and Earth structure are sufficiently refined that it is now possible to predict accurately the diurnal and semidiurnal earth and load tides for most sites (Agnew, 1995).

The ocean tides can be thought of as ocean surface gravity waves forced at tidal frequencies. The ocean wave spectrum extends from the periods of tides to periods much shorter than 1 sec. Waves longer than about 25 s (0.04 Hz) are called infragravity waves and the pressure signal from these waves can be observed at any ocean floor site (Filloux, 1980). Wave amplitudes in the infragravity wave band from 0.002 to 0.04 Hz rarely exceed 1 cm in deep water, but the deformation due to infragravity wave loading controls vertical acceleration noise at sea-floor sites in the Pacific in this band (Webb, 1998). Infragravity waves are typically much less energetic in the North Atlantic and may be irrelevant for sea floor seismic observations during at least the summer months in that basin (Beauduin and Montagner, 1996; Webb, 1998).

The problem of deformation of the sea floor under the loading of infragravity waves has been studied extensively (Crawford *et al.*, 1999), and the deformation has been used to determine crustal structure at ridge crests. The pressure signal from ocean waves is evanescent in water depth with an e-folding distance equal to the wavenumber, so that higher-frequency waves are observed at the sea floor in shallower water. Significant pressure fluctuations are observed below about 0.03 Hz in 4 km water depth, and below about 0.045 Hz in 1 km water depth. The amplitude of the deformation increases rapidly with wave frequency so that the infragravity wave deformation signal is much larger in shallow water (Webb and Crawford, 1999). Recent observations of long-period noise off Monterey, California illustrated the twin problems of making long-period measurements on the sea floor near the coastline. Even at 1 km water depth, the infragravity deformation signal dominated the vertical component noise levels below 0.05 Hz, while strong ocean-floor currents overwhelmed the horizontal component observations even though the seismometer was mostly buried below the sea floor (Romanowicz *et al.*, 1998).

Infragravity wave amplitudes become large near coastlines where wave energy becomes trapped as edge waves to the

shoreline, but because wavelengths also become short in shallow water, the deformation signal does not penetrate far inland. Agnew and Berger (1978) show that noise levels near 0.01 Hz are high at coastal and island sites due to loading by edge waves. Edge waves are often a problem for sites on small islands and atolls. Borehole installations designed to optimize long-period performance may prove ineffective on atolls (G. Holcomb, personal communication, 1999) partly because of deformation noise from edge waves.

Recent work has shown that low-order normal modes of the Earth are persistently excited by some unknown mechanism. It is possible that edge waves could be the source for this excitation, although recent literature has associated this signal with atmospheric turbulence (Tanimoto, 1999). Infragravity waves coupling to seismic modes could also be the source of the broad spectral peak near 120 sec at some global stations noted by Peterson (1993). The infragravity wave signal otherwise fades quickly inland.

2.2 Atmospheric Pressure Variations, Winds and Currents; Tilt Noise

Ground noise on land at very long period (0.2 to 50 mHz) is usually associated with atmospheric pressure fluctuations. At these very low frequencies, vertical component seismometers react to changes in gravity as the mass of the atmosphere above a site changes with atmospheric pressure. At higher frequencies, the ground deforms under the fluctuating pressures associated with turbulence in the boundary layer (Murphy and Savino, 1975). Seismometers that are not fully sealed may also experience apparent accelerations due to buoyancy effects on the seismometer mass, and pressure fluctuations can drive long-period horizontal component noise by distorting the case of the seismometer or the walls of the vault (Savino *et al.*, 1972). Long-period seismometers are invariably sensitive to temperature changes and most installations include a means to seal the sensor from pressure fluctuations and some kind of insulating box to restrict the rate of change of temperature seen by the seismometer.

Zurn and Widmer (1995) show that vertical component noise levels between 0.2 and 1.7 mHz can be reduced by more than 10 dB by subtracting the scaled, locally recorded pressure signal from the vertical acceleration record, thereby improving the signal-to-noise ratio for normal mode observations. The method reduces noise levels at the station studied to below the Peterson low-noise curve (Fig. 1). Earth tide observations can also be improved using a similar correction (Warburton and Goodkind, 1977). At these long periods, the apparent vertical acceleration is caused by the gravitational attraction of the varying mass of the atmosphere above a site, which is reflected in the changes in barometric pressure.

At shorter periods, turbulence in the atmospheric boundary layer produces pressure fluctuations at the Earth's surface that cause significant deformation to depths a few tens of meters

below the surface. This noise source is a primary reason that seismometers at permanent stations are now usually installed beneath the Earth's surface in shallow (100–300 m deep) boreholes. For instruments on the surface, short-wavelength fluctuations produce a large tilt signal that makes the horizontal components particularly noisy.

Turbulent eddies are advected over the ground at velocities comparable to the wind velocity near the top of the atmospheric boundary layer. The characteristic period associated with an eddy is the size (wavelength) of the eddy divided by advection velocity. The e-folding length of decay of the deformation into the ground is about equal to the wavelength of the pressure signal over 2π . A typical wind speed is 10 m s^{-1} , for which the e-folding scale is 100 m at 0.016 Hz. Short-wavelength deformation signals are quickly filtered out, leading to large improvements in long-period horizontal component noise levels at shallow depths in boreholes. Noise levels for sensors in boreholes at depths of a few hundred meters become comparable to near-surface sites during calm days, leading Sorrels and Douze (1974) to propose that the remaining noise is due to atmospheric infrasound.

The analogues of wind on the ocean floor are ocean currents. These too set up a turbulent boundary layer with advecting pressure fluctuations (Webb, 1988). The deformation signal decays completely within a few meters depth below the sea floor because much lower velocities are associated with ocean currents than with wind (hence much shorter wavelengths).

Horizontal component seismometers are sensitive to tilt as the acceleration associated with gravity is rotated into each horizontal component. Agnew (1986) provides a review of tiltmeter measurements in the seismic band. It is not possible to discriminate tilt from horizontal acceleration using inertial sensors. For seismometers in a vault, tilt noise is associated with local deformation of the ground due to propagating pressure disturbances or with wind forces on nearby structures (trees, buildings, etc.). The apparent horizontal acceleration A_h is associated with ground tilt Ω as $A_h = g\Omega$. Noise levels in the band between 0.001 and 0.05 Hz of $10^{-16} (\text{m sec}^{-2})^2 \text{ Hz}^{-1}$ correspond to a root mean square acceleration of about $2 \times 10^{-9} \text{ m sec}^{-2}$ or root mean square tilt of 2×10^{-10} . This tilt corresponds to 1 mm in 4000 km, a very small tilt indeed.

Long-period horizontal component ambient noise levels in surface vaults are usually 10–30 dB above the vertical component levels measured at the same place due to tilt noise. Spectra from shallow (15 m) boreholes are considerably noisier than those from deeper (100 m) boreholes (Peterson *et al.*, 1976). Recent practice has placed three component seismometers in 100–300 m deep boreholes to reduce tilt noise. Murphy and Savino (1975) report that the effect of atmospheric pressure fluctuations on horizontal component noise is reduced by more than 90% at a depth of 150 m. Observations from deep continental boreholes show comparable long-period noise levels on horizontal and vertical components (Fix, 1972; Murphy and Savino, 1975).

It is usually possible on land to bury sensors below the surface to avoid the direct force of wind even for temporary installations. In contrast, ocean-floor instruments are typically dropped on the ocean floor and thus directly exposed to currents. Current-generated noise on the sea floor is usually caused by the direct action of current on the unshielded instrument (Duennebie and Sutton, 1995). Horizontal component noise levels on sea-floor sensors can be as much as 60 dB higher than vertical component noise levels at periods near 100 s due to tilt (Webb, 1998). Tilt noise will appear on vertical component records as well if the vertical component sensor is not very precisely oriented with the true vertical because it will include a horizontal component equal to the sine of the error in orientation. An error of only 0.5° represents a leakage of 1 part in 100 in amplitude between horizontal and vertical components. Maintaining a difference of 60 dB requires orienting the vertical component with the true vertical to better than 0.06° . Most vertical component records from the sea floor show evidence of tilt noise due to currents (including probably the spectra in Fig. 2). A post-recording rotation of the sensor axes using three component data can reduce long-period sea floor vertical component noise levels by 10–20 dB (Crawford and Webb, 2000). The differences between vertical and horizontal noise levels on land are usually much smaller because installations are better and because pressure-induced ground deformations are of longer wavelength and therefore produce smaller tilts. The typical half-degree accuracy in verticality associated with most seismic installations is sufficient to prevent significant leakage of tilt noise into the vertical. Vertical noise generated by atmospheric pressure fluctuations at land sites is mostly due directly to vertical motions of the ground.

Shallow-water sites can be intensely noisy because of strong currents (e.g., Romanowicz *et al.*, 1998). The very short wavelengths associated with pressure fluctuations due to ocean-floor currents suggest that sensors buried a few meters below the ground will be as quiet at long period as sensors at much greater depths (Webb, 1998). Burial of a seismometer at 2 m depth below the sea floor was found to be sufficient to reduce long-period horizontal component noise levels by about 60 dB compared to a surface instrument (Vernon *et al.*, 1998), but incomplete burial of the sensors at a site offshore of Monterey was insufficient to shield a long-period seismometer from strong ocean currents there (Romanowicz *et al.*, 1998). To date, instruments installed in ocean-floor boreholes have been noisier than or comparable to surface sites at long period (Fig. 2c), probably because of convection of sea water in the borehole (Beauduin and Montagner, 1996; Vernon *et al.*, 1998).

Tests on land show that horizontal component noise levels are more than 20 dB higher for seismometers in oil-filled boreholes compared to dry holes. The higher noise levels in the fluid-filled boreholes are attributed to convection currents. The geothermal gradient always provides a temperature gradient

that can drive convection. Horizontal component noise levels vary greatly between borehole sites even for dry boreholes. Holcomb *et al.* (1998) found that horizontal component noise levels at noisy holes could be substantially reduced by packing the borehole sensor into the borehole using sand, rather than using the standard locking mechanism. The sand prevents convection in the borehole. They suggest that a test of a good installation is that the long-period horizontal component levels should be comparable to vertical noise levels.

2.3 Single-Frequency Microseism Peak

The single-frequency, or primary, microseism peak occurs as a small peak in the spectrum between 0.05 and 0.1 Hz, just below the main microseism peak in frequency (see Figs. 1–3). This peak is associated directly with ocean waves. Energy is transferred between ocean waves and seismic waves through non-linear interaction of ocean waves and bathymetry (Hasselmann, 1963). Measurements from instruments in coastal regions show spectral peaks that track ocean wave frequencies incident at the coast, although this energy decays rapidly inland (Haubruch and McCamy, 1969). The peak is called the single-frequency peak because it mimics swell frequencies without the frequency doubling observed for the main microseism (or double-frequency) peak. Single-frequency amplitudes are much larger at coastal sites than observed either in the center of continents or on the deep ocean floor. The single-frequency peak seen on Taiwan is 20 dB larger than observed at Pacific sea-floor sites, and also of higher frequency because the lower-frequency swell components are attenuated traveling across the broad shelf around the island (Hedlin and Orcutt, 1989).

In the center of continents or of an ocean basin, the single-frequency peak is related to storm waves on remote coastlines (Cessaro, 1994). An analysis of LASA array from Montana shows energy is primarily carried as fundamental mode Rayleigh waves, although there is often a component of Love wave energy (Lacoss *et al.*, 1969). Most of the energy at LASA originated to the northwest of the array, although other directions were occasionally observed. The spectral amplitude of the single-frequency peak ranges from about $10^{-16} \text{ (m sec}^{-2}\text{)}^2 \text{ Hz}^{-1}$ to $10^{-15} \text{ (m sec}^{-2}\text{)}^2 \text{ Hz}^{-1}$ for the majority of continental sites (Fig. 1). The spectra deviating from this range tend to be coastal or island sites in Figure 1. The relative stability in amplitude for continental sites around the globe suggests persistent, stable sources. Holcomb (1998) reports on a persistent peak in the noise spectrum at 26 sec period that appears on seismometers worldwide. The source of this peak is unknown, but signals are largest during the southern winters and the amplitude of the peak is correlated between sites worldwide, although frequently barely above the background noise level. Smaller peaks of slightly different frequencies may also be present.

2.4 Detection Thresholds for Surface Waves and Long-Period Body Waves

It is evident that noise levels are sufficiently low at most seismic sites to allow the detection of seismic arrivals from distant, large earthquakes. Many of the normal modes of the Earth can be detected at the quieter sites from the largest events. Signal-to-noise ratios are estimated by comparing the root mean square (rms) noise levels with model signal amplitudes in 1/3 octave bands (Fig. 3a). Signal levels are estimated for a source range of 30° in this figure taken from Agnew *et al.* (1986). The 1/3 octave bands represent a useful and achievable bandwidth using digital filters. Signals are detectable in any band where the signal curves significantly exceed noise levels. The solid lines indicate surface wave and body wave amplitudes. The dashed curves extending the surface wave curves represent normal mode amplitudes. Estimates of maximum and minimum earth noise at global seismic stations are shown on the figure.

These curves are very approximate. Surface wave spectra vary greatly with source mechanism and depth. In general, surface waves from shallow events are barely detectable near 0.04 Hz at most sites from events exceeding about $M_W = 4.5$. The detection of lower-frequency surface waves and normal modes requires larger events. Body waves can be detected at frequencies below the microseism peak from events exceeding about $M_W = 4.5$ at most sites. Smaller events can be detected at smaller distances (Fig. 3b; from Heaton *et al.*, 1989).

Spectra from stations on the sea floor suggests similar detection thresholds for surface waves near 25 sec period and for long-period body waves as on land (Webb, 1998). The detection thresholds for pressure measurements for body waves and surface waves in the band from 0.05 to 0.1 Hz are also similar to vertical acceleration detection thresholds. However, horizontal component seismic data from the sea floor are invariably much noisier than vertical component data below 0.03 Hz because of tilt noise. This limits the detection of Love waves and *SH* body waves to periods shorter than about 25 sec. (Shallow burial of the sensor packages should make horizontal component noise levels more comparable with vertical component noise levels and improve detection thresholds enormously.) Vertical component noise levels below 0.03 Hz on the Pacific sea floor are noisier than at most continental sites because of deformation under infragravity waves. This makes detection of long-period (>100 sec) surface waves and normal modes difficult at typical sea-floor stations. Lower infragravity wave amplitudes in the North Atlantic may provide better SNR for these phases, at least in the quiet summer months. Webb and Crawford (1999) show that sea floor pressure data can be used to remove most of the infragravity wave deformation signal from vertical component data in the band from 0.001 to 0.04 Hz, leading to improvements of 10–20 dB in SNR for long-period surface waves recorded at sea-floor stations in the Pacific.

FIGURE 3 (a) Amplitude of seismic arrivals and vertical component noise levels in 1/3 octave bands against low- and high-noise models for Earth noise illustrating typical detection thresholds for surface waves and body waves for arrivals from teleseismic distances. (From Agnew *et al.*, 1986.) The dynamic range of several networks is shown. (b) Short-period noise levels and amplitude of seismic arrival amplitudes at regional and local distances. (Reproduced with permission from Heaton *et al.*, 1989.)

3. The Microseism Peak (0.1–0.5 Hz)

Wind couples energy first into capillary waves on the ocean surface. The ocean wave spectrum evolves toward longer period and higher amplitudes with fetch and with time as nonlinear mechanisms transfer energy toward longer periods. The wind climate and geography of the ocean basins establishes the ocean wave climate. Ocean waves couple into ground motion through several different mechanisms; some are local whereas others couple into elastic waves that travel throughout the Earth. Ocean waves are ultimately the primary source of seismic noise observed on broadband seismometers at continental, island, and sea-floor stations. The microseism peak near 0.15 Hz is generated by the interaction of ocean waves at sea and is prominent in all seismic noise spectra (Figs. 1 and 2).

Ocean waves couple energy into the elastic waves called “microseisms” through a well-understood nonlinear mechanism (Longuet-Higgins, 1950; Hasselmann, 1963). Two ocean waves of similar wavelength and frequency but traveling in nearly opposing directions interact to force an acoustic wave with a wavenumber equal to the difference in wavenumbers and a frequency equal to the sum of frequencies. The ocean waves can couple into an elastic wave of much larger wavelength and higher phase velocity if the propagation directions are nearly opposing because the difference in wavenumbers can be arbitrarily small. The acoustic wave in the ocean couples into elastic waves in the sea bed. There is an approximate frequency doubling as ocean wave energy couples in microseisms at half the wave period. Microseisms propagate primarily as Rayleigh waves in the Earth, but some energy is present as body waves, and heterogeneous Earth structure couples some energy into Love waves.

Microseisms on seismometers worldwide are mostly between 5 and 9 sec period and are the result of energetic ocean waves between 10 and 18 sec period. The limited scale of ocean storms and ocean basins limits the major components of the ocean wave spectrum to periods shorter than about 25 sec, with energetic waves longer than 20 sec fairly rare. In all noise spectra there is a very abrupt change in spectral levels at 0.1 Hz (Fig. 2).

Microseisms in this band propagate long distances as Rayleigh waves, so the noise level at any site depends on the interaction of ocean waves beneath storms and along coastlines all over the world. A typical e-folding scale for attenuation at these periods is thousands of kilometers (amplitudes are also affected by bathymetry and interaction with boundaries such as coastlines). The amplitude of the microseism peak at a particular site depends on its location compared to microseism sources and attenuation along the raypaths from those sources (Webb, 1992). Storms at sea act as prominent microseism sources that can be tracked from land.

4. Short-Period Noise and Short-Period Arrivals (>0.5 Hz)

4.1 Short-Period Band (0.5–10 Hz)—Microseisms

The microseism mechanism dominates sea floor noise up to frequencies of a few hertz. At slightly higher frequencies (5–10 Hz), noise associated with breaking waves may become important (McCreery *et al.*, 1993). The major difference between observations in the microseism band on the sea floor and on land is that there is almost always much more energy at frequencies near 1 Hz on the ocean floor than on land, often by more than 40 dB. (There is little difference in microseism spectral levels between land and the sea floor at longer periods.) This huge difference in spectral levels near 1 Hz has a profound effect on the relative detection thresholds for short-period teleseismic arrivals between the sea floor and on land.

It has been known for a long time that it is advantageous to site seismometer stations away from the coast to avoid the effects of coastal microseisms. A ranking of stations based on noise levels near 0.8 Hz shows a separation between coastal and interior sites (Peterson, 1993). Noise levels at 1 Hz at interior sites range from about 3×10^{-17} to about $5 \times 10^{-14} \text{ (m sec}^{-2}\text{)}^2 \text{ Hz}^{-1}$, while noise levels at coastal sites range from 10^{-13} to $3 \times 10^{-12} \text{ (m sec}^{-2}\text{)}^2 \text{ Hz}^{-1}$ (Fig. 1). Noise levels at the sea floor are yet again higher than at coastal sites most of the time, because of microseisms driven by ocean waves directly overhead ($>10^{-11} \text{ (m sec}^{-2}\text{)}^2 \text{ Hz}^{-1}$ Fig. 2). Short-period noise levels on land can also be affected by storm waves on nearby large lakes. Only during exceptional periods when extensive regions of calm winds surround the site can noise levels at sea-floor sites approach noise levels at the typical island site at short period (Webb, 1998).

Noise levels observed at station Kipapa on the island of Oahu are some 30 dB higher than the Peterson low-noise model at 1 Hz, but still 10–15 dB quieter than the sea-floor site south of Hawaii (Fig. 2). Microseisms with frequencies higher than about 0.3 Hz do not propagate efficiently from the oceans onto land, and once on land they attenuate quickly. This noise propagates in the deep ocean primarily as acoustic modes and most of the energy must be reflected or dissipated at the shelf edge before reaching coastal sites. Wilcock *et al.* (1999) found noise levels at 1 Hz diminished by about 0.1 dB km^{-1} with distance inland across Iceland, consistent with propagation of the microseism noise as surface wave modes. Stations near the center of the island of Hawaii were 10–15 dB quieter than the Kipapa station close to the coast on Oahu (Li *et al.*, 1994). Noise levels near 1 Hz on Kipapa were sufficiently high to severely limit the detection of short-period phases. In contrast, most of the longer-period energy (0.1–0.3 Hz) is transmitted onto shore, so that island sites tend to only be slightly quieter than sea-floor sites in the main microseism peak. Coastal

stations in Greenland are considerably noisier in the summer than in winter because the winter pack ice around Greenland prevents the local generation of microseisms by waves near the coast. In winter, the microseisms at these stations are dominated by distant storm sources (Harben and Hjortenberget, 1993).

4.2 Short-Period Noise (0.5–50 Hz)—Land

Seismic noise levels on land at frequencies above 0.5 Hz depend primarily on wind and on cultural noise, although the movement of water may also contribute. Every site has different characteristics depending on its distance from the ocean and from cultural sources, the wind climate of the site, and depth of burial of the sensor. A seasonal cycle is evident at some sites due to variations in wind, or water flow in nearby rivers. Spring runoff raises noise levels by up to 15 dB between 0.5 and 15 Hz at the NORESS array (Fyen, 1990). Necessary distances for siting stations away from moving water range from 60 km for very large waterfalls and dams to 15 km for smaller rapids (Wilmore, 1979).

High-frequency spectra during quiet intervals are quite similar among the quieter sites. The spectrum tends to be featureless under these conditions. The displacement spectrum follows a power-law dependence in frequency as $1/f^2$ (e.g., Bungum *et al.*, 1985). In acceleration the spectrum rises toward higher frequency as f^2 , until limited by attenuation or the coupling of the system to the ground. Wind noise is often the dominant source from 0.5 to about 5 Hz. Wind noise obviously depends on the strength of the wind and the character of the site. It is not unusual to see 20 dB increases in noise level near 1 Hz with changes from calm conditions to winds of 5 m sec^{-1} on instruments in surface vaults. The primary mechanism by which wind couples into high-frequency noise is probably by the direct action of the wind on trees, bushes, and other structures, although at lower frequency the pressure fluctuations associated with wind can directly drive motions of the ground. Wind becomes a detectable source of short-period noise for sites far from cultural sources at wind velocities above about 3 m sec^{-1} at surface sites and at 4 m sec^{-1} for subsurface sensors (Withers *et al.*, 1996).

The term cultural noise is used to describe any seismic noise associated with man or man-made machinery: power plants, factories, trains, highways, and even cattle. Cultural noise is in principle avoidable, although it is often impractical to site stations at sufficient distances away from cities or highways. Some rules of thumb suggest that it may be necessary to site stations as far as 25 km from power plants or rock-crushing machinery, 15 km from railways, 6 km from highways, and a kilometer or more from smaller roads (Wilmore, 1979). Noise travels further across competent rock than through alluvial filled valleys and “safe” distances may be from 1/2 to

2/3 of the values above depending on propagation path (Wilmore, 1979).

Cultural noise varies greatly between sites (e.g., Fig. 1). Noise levels can vary by 30 dB within a day and from day to day, so it is common to present ensembles of spectra by percentile ranking to allow discrimination between infrequent very loud sources and more typical background levels (e.g., Bungum *et al.*, 1985). Noise spectra often show a distinct diurnal or weekly character (e.g., Given, 1990). Noise levels are lowest in the early morning in data from the NORESS array, rising rapidly near 07:00 to levels sustained throughout the working day, to fall gradually through the evening hours (Fyen, 1990). Noise levels are lowest on weekends but increase during holidays because of higher traffic.

Sources such as power plants are narrowband, producing energetic lines in the spectrum at 50 or 60 Hz and harmonics and subharmonics (e.g., 30 Hz, 25 Hz) depending on location. The NORESS array data included lines at 6, 12, and 17 Hz due to reciprocating saws in a nearby sawmill (Fyen, 1990). It may be possible to remove some narrowband noise through application of digital or analog filters. Other types of machinery may also produce narrowband peaks, but the frequencies of the lines may shift with time as motor speed varies. These noise sources are more difficult to remove.

Comparisons of noise spectra from surface vault installations and borehole installations have repeatedly shown significant improvements in SNR for high-frequency phases from borehole installations at depths as shallow as a few meters (e.g., Aster and Shearer, 1991). The signal-to-noise ratio for high-frequency arrivals can be optimized by choosing sites with a lossy blanket of weathered near-surface material (Withers *et al.*, 1996). Large reductions in noise level may be seen in the first 5 m between the weathered rock of the surface and the more competent rock in the borehole. The frequencies of local seismic arrivals are slightly higher in boreholes because attenuation is less, which may also enhance the SNR.

Wind noise couples into open boreholes and covering open boreholes can reduce wind noise considerably; the wind may drive pressure fluctuations that propagate down the borehole. Most comparisons of borehole and vault noise levels show 10–30 dB lower noise levels in the boreholes, with most of the reduction in noise level occurring in the first 100 m (Young *et al.*, 1996). Broadband spectral levels fall with increasing depth into the borehole, but narrow spectral lines due to cultural sources may show less depth dependence (e.g., Galperin *et al.*, 1978) and therefore be of increasing importance with depth. Wind-generated noise couples mostly into surface modes, but cultural noise must couple at least partly into body waves that can propagate to depth (Carter *et al.*, 1991). The difference in noise levels between vault and borehole sensors tends to be largest when data from poorly prepared surface sites are compared with borehole data. Given (1990) found only a factor of 2 improvement in high-frequency SNR for a shallow borehole at a

site in the former USSR compared with a well-prepared surface vault.

4.3 Short-Period Noise (0.5–50 Hz)—Sea Floor

The sea floor in the band from 0.5 to 5 Hz is almost invariably noisier than the typical land site because of microseisms generated by small-amplitude, high-frequency ocean waves that can be produced by even quite light winds. Locally generated microseisms maintain sea-floor noise levels some 40 dB above land sites most of the time, but noise levels may fall significantly during long intervals of calm winds.

Noise levels above 1 Hz are directly related to wind and wave conditions over the site, although noise levels “saturate” with little increase in noise levels above a saturation wind velocity that is frequency-dependent (McCreery *et al.*, 1993). Saturation occurs because ocean wave spectra saturate at high frequency, leading to a constant rate of excitation of microseisms, which is balanced by a constant rate of dissipation of the microseisms within a fairly small area (Webb, 1992). The noise spectrum approaches saturation near 1 Hz for a wind velocity of only about 5 m sec^{-1} (10 knots). Records from several sites show relatively constant values of 1 Hz noise except during rare intervals when local winds drop to near calm conditions for at least a day. During these intervals, noise levels can drop by 20 dB or more (Webb, 1998; Wilcock *et al.*, 1999).

One expects to see winds exceeding 5 m sec^{-1} over most sites in the oceans most of the time, so the average sea-floor site is very noisy near 1 Hz most of the time. A notable exception is the Arctic ocean, where the ice cap prevents the excitation of the ocean surface waves that ultimately couple to noise in the microseism peak. The Arctic sea floor has been observed to be very quiet near 1 Hz during the winter (Webb and Schultz, 1992). Parts of the North Atlantic and Indian oceans can also experience long intervals of near calm conditions during the summer months and may provide quiet sites for detection of short-period body waves (Webb, 1998). Most sites in the Pacific seem to be noisy most of the time (McCreery *et al.*, 1993).

It is not obvious that installing seismometers within sea-floor boreholes will necessarily reduce microseism noise levels. Energy is coupled from ocean waves into acoustic waves and then into elastic waves below the sea bed. The wavelength of a 1 Hz acoustic wave in the ocean is 1.5 km, and the wavelengths of the Rayleigh wave modes below the sea bed are even larger. If only these modes were present, noise levels would not be expected to fall until depths of several kilometers were reached, beyond the present range of ocean drilling. However, some improvement in signal to noise is expected at shallow depths because microseisms are scattered by bathymetry and by topography at the sediment–basement interface into short-wavelength (Stoneley) shear modes

(Bradley *et al.*, 1997). These slowly propagating shear modes are trapped to the sediment–water interface with displacements that decay away from the sea floor. Correlation lengths measured between elements of a small-aperture array of OBSs were between 100 and 200 m at frequencies above 0.4 Hz (Schreiner and Dorman, 1990), a result that requires significant energy in short-wavelength waves.

Data from seismometers locked at three depths in a borehole near the Bahamas show that the difference between sea-floor and borehole noise levels increases rapidly with frequency and depth, consistent with much of the noise at the sea floor propagating as Stoneley waves (Bradley *et al.*, 1997). There are obvious differences in the structure of borehole and ocean-bottom noise spectra. The deep spectra closely follow a power-law dependence on frequency with a slope of 80 dB/decade. In contrast, surface spectra show significant peaks in the band around a few hertz associated with the Stoneley modes.

The difference between the vertical noise level at 1 Hz on the sea floor and at depth increases from 6 dB at 10 m depth to 10 dB at 100 depth. At higher frequencies, the vertical spectra from the borehole sensors at 10, 70, and 100 m depth differ by less than 3 dB but are 10–15 dB quieter than at the sea floor. Signal levels at depth are also smaller (because of changing impedance) and the resulting improvement in signal-to-noise ratio is near zero at 0.2 Hz, increasing to more than 10 dB at 5 Hz. On the horizontal components, the decrease in noise levels is larger, reaching 15 dB at 70 m depth at 1 Hz and 20 dB at higher frequencies. Most of the improvement occurs in the first 10 m for frequencies above 1.5 Hz, but below 1 Hz the sensor at 10 m depth is only a few dB quieter than at the sea floor. The depth dependence at 0.3 Hz was consistent with propagation as fundamental mode Rayleigh waves with little difference in vertical and horizontal component noise levels between sea-floor and borehole sensors.

High-frequency noise (5–50 Hz) on the sea floor tends to be associated with man-made (cultural) sources. The study of noise in the sea has been much more systematic and extensive than on land as part of the field of ocean acoustics, where noise sources are often military targets. A good recent review of “low-frequency acoustic noise” (<100 Hz) can be found in Richardson *et al.* (1995). The important sources of noise transition from the microseism peak below 5 Hz, through wind-generated noise between 5 and 10 Hz, to primarily cultural (shipping) at higher frequencies. Wind noise becomes important again at much higher frequencies through wave breaking.

The important components of shipping noise include cavitation of propellers and noise from vibration of machinery. Distinct lines associated with generators (50 or 60 Hz) or with other machinery (motors, generators, thrusters and pumps, etc.) make up much of the shipping noise, with noise levels peaking between 10 and 100 Hz. The lowest-frequency components are associated with rotation of propellers. Large ships such as supertankers produce “blade lines” at frequencies of

7 Hz or lower, with many higher harmonics (Richardson *et al.*, 1995). Noise levels vary with intensity of shipping traffic. High-traffic areas can be 20–25 dB noisier than regions remote from shipping. The transition band (5–10 Hz), above the microseisms and below shipping noise, provides relatively quiet conditions. This allows detection of oceanic P_n and S_n phases (also known as P_o and S_o) to great distances (Butler *et al.*, 1987) from moderate magnitude oceanic events.

Another low-frequency source for some locations is large whales. Blue and fin whales produce very loud calls at frequencies as low as 16 Hz that are easily seen locally on sea-floor seismometers. In some special locations such as the Gulf of Maine, whale calls can be so frequent as to interfere with active source seismic experiments. Other sources of noise in the seismic band include noise associated with the movement of ice in the polar regions, seismic sources (airguns), and offshore drilling (Richardson *et al.*, 1995).

4.4 Detection Thresholds for Short-Period Body Waves

Approximate detection thresholds for teleseismic (30°) and local short-period P waves for sea-floor and continental sites can be estimated from Figures 3 and 4. The amplitudes of short-period arrivals decrease with increasing range because of geometrical spreading, but detection thresholds also depend on the frequency content of the arrivals, which depends on

attenuation. Attenuation increases with increasing range but is also path-dependent. The rapid decrease in microseism noise with increasing frequency above the microseism peak means that small changes in frequency content of arrivals may be associated with big differences in detection thresholds. For example, shear waves at teleseismic distances may be too low in frequency to be seen at all above the microseism peak, particularly at sea-floor stations where noise levels are high. Attenuation along the typical raypath for a compressional wave from a distant event to a continental station restricts the frequency content of the typical P wave to a few hertz. This is sufficiently high frequency to put the arrival above the significant energy in the microseism peak at a land site, but not at a sea-floor site.

Figure 3 suggests that detection thresholds at most land sites for P waves from distant events ($>30^\circ$) will be roughly magnitude M_W 4.0, with slightly lower values for the quieter sites and much higher detection thresholds for the noisier island sites. This is in rough agreement with more careful estimates of detection thresholds for groups of stations. Recent estimates for the detection threshold for events globally using available seismic arrays range from about M_W 3.5 for heavily instrumented areas such as Europe to greater than M_W 4.5 for remote regions of the world's oceans (e.g., Kvaerna and Ringdal, 1999). Figure 3 suggests that all stations will detect S wave arrivals from events as small as about M_W 2.5 at close range (100 km). Efforts to detect small nuclear bomb tests

FIGURE 4 Same as Figure 3a for sea-floor sites for (a) vertical acceleration, and (b) pressure with noise levels from an atypically quiet (calm wind) interval and from a more typical noisy (windy) interval. Signal amplitudes are modeled for three different values of attenuation (t^*). High noise levels near 1 Hz make it difficult to detect short-period teleseismic body wave arrivals.

have focused on detecting high-frequency P_n and S_n arrivals at regional distances. P_n is detectable at frequencies up to 50 Hz at 500 km and at distances up to 1500 km at 10 Hz from magnitude M_L 3.0 events.

High noise levels near 1 Hz and high attenuation in the upper mantle (which removes the higher-frequency components of the P wave) conspire to make detection of short-period teleseismic P waves difficult at many sea-floor sites. Only short-period P waves from the very largest events ($M_W > 7$) can be detected (Blackman *et al.*, 1995) and then only with poor SNR. Wilcock *et al.* (1999) have made a systematic study of the wind statistics over the world's ocean-floor ridges to look for regions where long intervals of calm winds are more common. In these regions noise levels will often be 20 dB quieter than the typical site at saturation. The lower noise level is associated with detection thresholds several magnitude units smaller.

Figure 4 shows noise in 1/3 octave bands from a site on the sea floor during a typical noisy period and during one of the rare low-wind days from the MELT experiment. Teleseismic detection thresholds at the sea floor depend on attenuation below a site represented by the value of t^* shown on the model curves for p -wave amplitude for earthquakes of magnitudes 5.5, 6.5, and 7.5. The microseism noise spectrum falls quickly with increasing frequency, so detection thresholds are lower at low-attenuation sites because the P wave has more high-frequency energy. The model curves suggest that only the largest earthquakes ($M_W > 7.5$) will be detected, and then only with very poor SNR at typical noisy sea-floor sites near ridge crests (where attenuation is high). The detection threshold at sites on older oceanic crust, and for arrivals from deep earthquakes for which attenuation is less ($t^* = 1$) are lower ($M_W \approx 6$). Finally at sea-floor sites that see long intervals with calm conditions overhead, the detection threshold may fall as low as $M_W = 5.5$. Detection thresholds at local and regional distances for sites on the sea floor are much lower because the frequency content of the arrivals is above the microseism peak where noise levels are much lower. Local events detected during microearthquake studies on ridge crests range from $M_W -1.5$ to 2.0.

Lower noise levels within sea-floor boreholes lower detection thresholds for short-period body waves from the M_W 7.5 expected for noisy sea-floor sites (saturated microseism spectrum) to about M_W 6.5 and detection limits for quiet sea-floor noise conditions should be below M_W 5.5. Butler and Duennebie (1989) report on teleseismic earthquakes recorded by a borehole seismometer during a two-month recording period that included 15 nuclear explosions. Only the largest nuclear blast ($5.6 m_b$) was recorded. The authors note the importance of the high frequencies (6.5 Hz P wave) present in the blast seismogram in the detection of this event. The smallest earthquake observed was $5.4 m_b$; all other teleseismic earthquakes seen were greater than $6 m_b$. The station was on old oceanic crust with correspondingly low attenuation in the

lithosphere so that high-frequency S waves were observed from regional events.

Orcutt and Jordan (1986) report on detection thresholds from a sensor in a borehole in the western Pacific. Detection limits increased from about $5.2 m_b$ at a distance of 40° to about $5.6 m_b$ at 80° . This is a site where light winds are expected more than 73% of the time, suggesting that noise levels should be low near 1 Hz. This low detection threshold is consistent with the low-noise model of Figure 4a combined with a 10 dB improvement in signal-to-noise ratio due to the borehole installation, particularly if the observations are associated with deep earthquakes from the subduction zones of the western Pacific, with signals propagating along low-attenuation paths. Regional earthquakes could be detected at a lower threshold ($4.6 m_b$) because of energy propagating as high-frequency oceanic P_n and S_n waves (also called P_o and S_o). These phases can be detected at great distances (Butler *et al.*, 1987) from moderate magnitude oceanic events because the frequency of the arrival is above the microseism noise.

US Contribution to Digital Global Seismograph Networks

Charles R. Hutt, Harold F. Bolton, and L. Gary Holcomb

Albuquerque Seismological Laboratory, US Geological Survey, Albuquerque, New Mexico, USA

This chapter summarizes the contribution to digital global seismograph networks by the United States, and provides information about station installation practices. The global effort is coordinated by the Federation of Digital Broad-Band Seismograph Networks (FDSN). Its membership comprises groups responsible for the installation and maintenance of broadband seismographs either within their geographic borders or globally. A brief summary of FDSN is given in Chapter 81, and detailed information of FDSN is given at their Web site <http://www.fdsn.org/>. Any use of trade, firm, or product names is for descriptive purposes only and does not imply endorsement by the US Government.

1. Motivation for Digital Seismograph Systems

1.1 Limitations of Analog Systems

One of the very first seismographs known to exist early in the Christian era, the Chinese *Kan Shin Gi*, could be called digital. During an earthquake, when a suspended ball fell out of a dragon's mouth into a frog's mouth on one side of this instrument, the earthquake was presumed to have occurred somewhere along a line defined by the center point of the instrument and the dragon whose ball had dropped. This amounts to a binary digital indication (1 fallen ball = earthquake, 0 fallen balls = no earthquake). However, most seismographs since that time, until the late 1960s, have been analog recording seismographs. That is, a trace recorded (as a function of time) on a piece of paper or other medium serves as an analog of magnified ground motion.

Analog seismograms gave us a first glimpse of the internal structure of the Earth. In 1911 Mohorovičić viewed the base of the crust. In 1936 Inge Lehmann differentiated the inner and outer core. The travel-time tables established by Jeffreys and

Bullen in the 1930s are still in use today. The millions of measurements made from analog recordings compiled by the International Seismological Centre (ISC) continue to be a rich source for research.

There are, however, several limitations of analog recordings:

- **Small dynamic range.** The ratio of the smallest visible trace displacement to the largest capable of being recorded on the medium used is usually no more than a factor of 100 or so (40 dB). For example, the well-known World Wide Standardized Seismograph Network (WWSSN) used 300 mm wide photographic paper. Under the best possible conditions (when the trace was in the center of the paper), and assuming that the smallest signal normally resolvable is 1 mm, then the dynamic range is 300/1, or almost 50 dB. But when the recorded trace is near the beginning or end of the record, the maximum available peak-to-peak amplitude is only 40 mm, so the dynamic range here is only 40/1 (32 dB). Electronic analog recording media such as FM tape suffer from similar small dynamic range capabilities (50–60 dB at best). Note that the range of ground motion from the lowest-noise sites on Earth to the largest accelerations experienced near the epicenter of great earthquakes exceeds 200 dB (a factor of more than 10^{10}). Because high-magnification seismographs are overdriven easily by large events, it is necessary to operate parallel low-gain seismographs whenever possible.
- **Slow to process.** Analog records are normally analyzed by hand. In the early 20th century, there were a limited number of seismograph stations and each station had one or more dedicated professionals who analyzed the seismograms. The WWSSN consisted of about 110 concurrently operating stations and most of these reported phase times, polarities, and amplitudes to the USGS National Earthquake Information Center (NEIC) in the

United States. Even so, NEIC had to employ several analysts to read WWSSN records for those stations not reporting. Manual analysis of analog records is labor-intensive and does not yield as much information as digital recordings.

- **Low information yield.** A majority of analog seismographs recorded narrowband filtered traces, resulting in simplified waveforms. Narrowband seismograms do not yield the complex information and spectra needed for modern source mechanism analyses and underestimate the total energy output of an earthquake. This is especially true for large earthquakes that produce seismic energy outside the preselected bands recorded. The main types of information obtained from analog recordings include phase time, period, amplitude, and polarity of first motion. These parameters allow the calculation of epicenter and magnitude, and give a rough estimate of the source mechanism. Depth phases and core phases also give information about event depth and the gross average velocity of the core and mantle. However, it is quite difficult to use analog recordings to stack many thousands of traces. Data-intensive processing necessary for seismic tomography would be impossible with analog data, as would much other automated processing that is now routine.
- **Difficult to store.** Paper recordings, film, and analog magnetic tapes are examples of analog media that are difficult to store over extended periods of time. Photographic paper and film deteriorate rapidly with age and exposure to light, and must be kept in a dark, cool, dry place. Analog magnetic tape also deteriorates with age. Signals become harder to read and SNRs decrease as apparent background noise levels on the tape increase.

Notwithstanding their limitations, there are millions of analog recordings in existence. It is not too late to convert many of these to digital format for permanent storage. One example is the set of several million film chips of WWSSN seismograms currently in storage at the USGS Albuquerque Seismological Laboratory. The USGS has funded a pilot project to scan at very high resolution several interesting sets of these film chips for evaluation by researchers. If the images are of sufficient quality, and if additional funding and a feasible way of scanning large numbers of the chips can be found, then there will be a large number of potentially quite useful seismograms available in digital form (as scanned images, not digitized traces).

1.2 Advantages of Digital Systems

With the advent of electronic digital computers in the 1950s, many seismologists realized that there would be huge advantages to digitizing their analog records. This would allow automated processing, including the calculation of auto- and

cross-correlation functions, Fourier transforms, and a vast number of other things. At the beginning of the digital age, computers were expensive monstrosities relegated to large rooms in research laboratories. Before seismic data had begun to be recorded digitally, many a graduate student ruined his or her eyes on the manual digitization of analog seismograms so that some special digital technique could be applied. Not until the late 1960s had it become feasible to directly digitize seismometer signals at a few selected observatories and thus begin to save the eyes and nerves of graduate students.

There are many advantages of digital seismograph systems:

- **Large dynamic range.** The basic dynamic range of a good seismometer, even without feedback electronics, is usually quite large. For example, the WWSSN short-period seismometer ("Big Benioff") has a clip level of 10^{-3} m peak, and can resolve signals as small as 10^{-9} m, and so has a dynamic range of about 10^6 (120 dB). A good 16-bit digitizer has a dynamic range of 96 dB, which is about 2 orders of magnitude larger than an analog recording system. Modern 24-bit digitizer systems have a dynamic range of about 140 dB or better (a factor of 10^7) (see Fig. 1). (Note that a WWSSN paper record would need to have a width of 10 km to match this dynamic range.) Many modern broadband seismometers utilizing electronic feedback can match or exceed the dynamic range of these digitizers. The combination of high dynamic range digitizers and seismometers results in digital seismograph systems capable of resolving background

FIGURE 1 Illustration of the relative dynamic range and bandwidth of a well-known analog system (WWSSN short-period and long-period) and a modern 24-bit digital system (the GSN System).

seismic noise at the lowest-noise sites on Earth while remaining on-scale for most of the largest earthquakes, without the requirement to record a separate low-gain channel. This capability has obvious advantages in processing the recorded signals, as two separate channels need not be “patched together” to obtain a continuous time-series.

- **Fast to process.** Automated signal detection and processing by digital computer is possible once the data have been digitized. Such automated signal and phase detections may be used in event associator logic to determine which of many possible events each phase detection belongs to, allowing fully automated epicenter and magnitude determination (to be reviewed later by a human analyst).
- **High information yield.** The use of high dynamic range digitizers and broadband seismometers allow the recording of ground motion without filtering. Older analog seismographs achieved high magnification settings in the short-period and long-period bands by filtering out the main source of noise: the 6–8 sec microseismic band. However, this also filtered out useful information, as energy in the 6–8 sec band is useful in determining the source mechanism of earthquakes. High dynamic range digital seismographs can record across the entire band of interest, including the microseismic band, without filtering because they are capable of resolving ground motion in all frequency bands even in the presence of high microseismic noise. The analyst may then apply digital filters *after* the data have been recorded, without permanent loss of information. In addition, many other types of processing may be applied, because the data are already in digital form. These include spectral analysis, centroid moment tensor analysis, seismic tomography, trace stacking, and background noise analysis at each station.
- **Easy to store.** Once the ground motion data have been recorded in digital format, they may be copied onto any number of media without any loss of fidelity whatsoever. This is not the case with analog recordings, which are degraded every time a copy is made. Thus, as technology continues to bring media with greater capacity and faster access, it is possible retain the full bandwidth of the digital data across each transcription.

2. History of Development of Some US Sponsored Digital Networks

No discussion of modern instrument development can take place without discussing the various types of digital seismographic networks developed over the years. Some of the digital networks developed and installed by the United States are listed below in time order of their development.

TABLE 1 HGLP Stations

Code	Location	Years of Operation
ALQ	Albuquerque, New Mexico, USA	1972–1978
CHG	Chiang Mai, Thailand	1972–1976
CTA	Charters Towers, Australia	1972–1976
EIL	Eilat, Israel	1972–1979
KIP	Kipapa Gulch, Oahu, Hawaii, USA	1972–1978
KON	Kongsberg, Norway	1972–1978
MAT	Matsushiro, Japan	1972–1977
OGD	Ogdensburg, New Jersey, USA	1973–1979
TLO	Toldeo, Spain	1972–1978
ZLP	Zongo Valley, Bolivia	1972–1976

2.1 High-Gain Long-Period (HGLP)—1972 to 1979

This was a network of 10 globally distributed long-period stations developed by the Lamont–Doherty Geological Observatory (now known as the Lamont–Doherty Earth Observatory) for the purpose of earthquake and nuclear monitoring research. Station information is given in Table 1. The Teledyne Geotech long-period seismometers, set to a natural period of 30 sec, were installed inside steel hemispherical sealed tanks for thermal and pressure isolation. These were connected to 100-sec galvanometers in phototube amplifiers (PTAs) that amplified the seismometer signals and shaped the narrowband long-period displacement response with a peak at 40–50 sec period. A 16-bit Astrodata data logger recorded the data at one sample per second on half-inch 7-track computer tape. The HGLP stations were able for the first time on a global scale to resolve the natural low in the Earth’s background spectrum near 50 sec period. However, the seismometers in tanks were sometimes installed in relatively shallow tunnels (~10 m overburden). Also, even though great care was used to secure the tank bottoms rigidly to the tunnel floor or pier, the flat bottoms of these tanks would flex during atmospheric pressure changes. Both the shallow installations and the flexing tank bottoms resulted in noisy horizontal data during periods of moderate to high winds.

2.2 Seismic Research Observatories (SRO)—1974 to 1993

The noisy long-period horizontal data obtained from the HGLP network spurred the development of a broadband borehole seismometer that could be installed at 100 m depth in standard 7-inch oil well casing. Studies had shown that the tilt-generated long-period noise, resulting from wind and passing weather fronts, attenuates rapidly with depth in hard rock. It was also desirable to be able to locate seismic stations at sites other than abandoned mines or expensive hand-dug tunnels. The Teledyne Geotech KS36000 seismometer developed for this program was installed at 13 locations around the world known as the Seismic Research Observatories (see Table 2).

TABLE 2 SRO Stations

Code	Location	Years of Operation
ANMO	Albuquerque, New Mexico, USA	1974–1989
ANTO	Ankara, Turkey	1978–1992
BCAO	Bangui, Central African Republic	1979–1990
BGIO	Bar Giyyora, Israel	1986–1988
BOCO	Bogota, Colombia	1978–1987
CHTO	Chiang Mai, Thailand	1977–1992
GRFO	Grafenberg, Germany	1978–1993
GUMO	Guam, Mariana Islands, USA territory	1975–1991
MAIO	Mashhad, Iran	1975–1978
NWAO	Narrogin, Australia	1976–1991
SHIO	Shillong, India	1978–1985
SNZO	South Karori, New Zealand	1975–1992
TATO	Taipei, Taiwan	1976–1992

The broadband data output had a flat response to acceleration from 0 to 1 Hz, but was amplified and spectrally shaped into two narrow bands before recording: 0.02–0.05 Hz (long period or LP band) and 1–3 Hz (short period or SP band). The LP data were recorded continuously at one sample per second (sps), while only triggered SP events were recorded at 20 sps. The digitizer was a 12-bit gain ranging device with an overall recording range of approximately 132 dB.¹ However, overall system noise levels (including digitizer, seismometer, and filter) were considerably higher than one bit at the highest binary gain step, so the actual recording range was closer to between 110 and 120 dB. Also, there were some noise problems caused by inaccurate binary gain steps, resulting in nonlinear representation of the data. Available dynamic range in the presence of earth noise was further reduced by using a high sensitivity setting. This resulted in the digitizer least significant bit (LSB) at the highest binary gain being about 60 dB below earth noise at a quiet site in the SP band, and about 30 dB below earth noise in the LP band. Available recording range (from quiet site earth noise to clip level) was only about 60 dB in the SP band and about 95 dB in the LP band. The data were recorded on half-inch 9-track computer tapes.

2.3 Modified High-Gain Long-Period Stations (ASRO)—1976 to 1993

A decision was made after the beginning of the SRO program to replace the Astrodata data logger at four of the HGLP

¹ The highest-resolution commercially available digitizers available were 12 bits, allowing only 66 to 72 dB recording range. Since a recording range of 120 dB was required for the SRO systems, the digitizer manufacturer attached a 11-step binary gain amplifier (BGA) to the input of the 12-bit digitizer. The gain steps were 2^0 (unity gain) up to 2^{10} (gain of 1024). Small signals resulted in a BGA setting of 2^{10} , thus amplifying these signals to a level large enough for the 12-bit digitizer to resolve. Larger signals resulted in correspondingly smaller BGA gain settings, so that the digitizer would not clip. The largest signal that could be digitized was 10 volts at a BGA setting of 2^0 or a gain of unity.

TABLE 3 ASRO Stations

Code	Location	Years of Operation
CTAO	Charters Towers, Australia	1976–1987

stations with SRO-type data loggers, and to change the HGLP amplitude response to more closely match that of the SRO. Also, a short-period vertical Johnson–Matheson seismometer and amplifier/filter were added so that there would be SP data as well as the existing LP data. This made those four stations (plus a new one in Afghanistan) similar to SRO stations except that the seismometers were in seismic vaults rather than in boreholes. These stations (see Table 3) were known as Modified High-Gain Long-Period stations, or Abbreviated SRO stations (hence the ASRO acronym). The digitizer was exactly the same as in SRO stations: a 12-bit digitizer driven by a 11-step binary gain amplifier. The displacement response from the long-period seismometer/amplifier combination peaked at period of about 28 sec. The short-period displacement response peaked at about 3 Hz. The useful dynamic range (from earth noise to clip level) was limited by high-sensitivity settings, as in the SRO systems.

2.4 Digital World Wide Standardized Seismograph Stations (DWWSSN)—1981 to 1993

A desire for better geographic coverage than provided by the HGLP, SRO, and ASRO networks resulted in the idea of attaching digital acquisition systems to some existing WWSSN stations in appropriate areas. This was accomplished as follows: Amplifiers and filters were attached to the output of the standard WWSSN SP and LP seismometers. These amplified and band-shaped signals were digitized by a 16-bit analog-to-digital converter and recorded on half-inch computer tape under control of a microcomputer system. The dynamic range of the data acquisition system was roughly 90 dB. A digital (manually set) clock module, designed specifically for installation in the WWSSN timing console, provided digital time signals for time tagging the data. In addition to standard narrow SP and LP bands, a band known as “intermediate period” (IP) was recorded. The IP band was basically a low-sensitivity recording of the raw unfiltered output of the Press–Ewing long-period instrument, and was one of the first attempts by the United States to record broadband data. LP data were recorded continuously at 1 sps, whereas the recording of IP (10 sps) and SP (20 sps) data were triggered by a rudimentary event detector. These stations are known as DWWSSN (see Table 4).

2.5 China Digital Seismograph Network (CDSN)—1986 to 1999

The nine original stations of the CDSN were installed in cooperation with the State Seismological Bureau (SSB) of China beginning in 1986, with the Lhasa, Tibet (LSA) station being added in 1991 (see Table 5). (The SSB has since changed its name to the China Seismological Bureau, or CSB.) The CDSN was the first US-sponsored cooperative network where true broadband seismometers (20-sec Streckeisen STS-1 instrument) were used. Data from the STS-1 seismometers were split into three separate bands that were sampled and recorded as follows:

- VLP, velocity response peaking at 200 sec period, 0.1 sps, continuous
- LP, flat to acceleration 30–500 sec, 1 sps, continuous
- BB, flat to velocity 5 Hz to 20 sec, 20 sps, events only

Chinese DJ-1 1-sec seismometers were used as the short-period instrument, and were connected to the digitizer through a short-period amplifier/filter. The SP data were sampled at 40 sps and

recorded on an event basis. The digitizer was a gain-ranged type, similar to that used in the SRO and ASRO systems. However, there were only four gain steps: 1, 8, 32, and 128. This gain-ranging amplifier was connected to a 14-bit digitizer, resulting in an overall recording range of 126 dB. A digital clock that was set manually by comparison to WWV time signals provided time tagging. The data were recorded on quarter-inch cartridges.

2.6 International Deployment of Accelerometers (IDA)—1975 to 1995

This section was contributed by Peter Davis, IDA Group, University of California, San Diego

The IDA network was originally established to provide global digital measurements of the Earth's normal modes, at periods from (roughly) 60 to 3600 sec. The network, sponsored by Cecil and Ida Green and the National Science Foundation, was operated by the Institute of Geophysics and Planetary Physics at the University of California, San Diego (see Table 6). The sensor (for vertical motion only) was a Lacoste–Romberg underwater gravity meter, of standard Lacoste zero-length spring design, housed inside a pressure-tight container with temperature control. Electronics (using electrostatic position sensing and feedback) were added to this sensor to make it a force-balance system with a flat response to acceleration. The

output of this system was passed through two filters: a Tide channel, which was a low-pass filter flat below 16 mHz, and a Mode channel with additional gain and flat response from 0.3 to 16 mHz. Both channels were digitized using a 12-bit fixed-gain digitizer, and recorded on digital cassette tapes. The Tide channel was recorded with a sampling interval of 10 min, and the Mode with an interval of 10 sec. Time tagging was provided by the data-recorder, using an internal digital clock, which was set manually by comparison with WWV time signals when the tapes were changed (roughly every 10 days).

2.7 Global Seismographic Network (GSN)—1988 to the Present

The GSN was the first US effort to collect high-fidelity broadband seismic data at seismological observatories uniformly distributed around the globe. It is sponsored by the Incorporated Research Institutions for Seismology (IRIS), the US National Science Foundation (NSF), and the US Geological Survey (USGS). The US Air Force Office of Scientific Research and the Green Foundation have provided additional funding. The USGS Albuquerque Seismological Laboratory (ASL) and the IDA group at the University of California, San Diego, are the two network operators responsible for installing, maintaining, and collecting data from the stations of the GSN. Although there are several different versions of early prototype seismic data acquisition systems, the relevant features are in general as follows:

- Continuous (rather than event-detected) recording of broadband data at 20 sps.
- Flat response to earth velocity from 0.003 Hz to 5 or 10 Hz.
- The capability to resolve background seismic noise at the lowest-noise sites, without clipping the largest conceivable signals from great earthquakes, over a range of frequencies from earth tides to tens of Hz (see Fig. 1).
- Accurate time tagging without dependence on a human to check or set the clock.
- Real-time telemetry of data to data centers.

These capabilities are achieved through the use of low-noise very broadband (VBB) primary seismometers in conjunction with high-frequency broadband or short-period seismometers and low-gain accelerometers. High-resolution (24-bit) digitizers providing at least 140 dB dynamic range are used. Time tagging, accurate to better than 1 msec, is provided by Global Positioning System (GPS) clocks. Data are recorded on high-capacity cartridge tapes and mailed to data collection centers. Also, as Internet connections and other inexpensive communication links become more available worldwide, an ever-increasing number of GSN stations are sending real-time data to data centers.

3. Seismic Installations in Boreholes

Borehole seismology is a relatively new technology, having developed over the last 30 y or so as compared with the relatively long period over which seismological science as a whole has been evolving. In the early years of seismology, installing a seismometer in a borehole was virtually impossible because of the relatively large physical size of the instruments. As seismological technology matured, the instruments became smaller and it became more practical to consider borehole installations as alternatives to surface vaults or installations in deeper abandoned mine tunnels. There are several reasons for placing seismic instrumentation in boreholes. These include reduced noise levels, temperature stability, and reduced pressure variability.

Experience gained over many years of installing both short- and long-period sensors by many individuals and organizations has shown that sensor systems that are installed at depth are usually quieter than those installed at or near the surface of the Earth. Therefore, abandoned underground mines are frequently used, when available, as sites for low-noise seismological stations. Otherwise, a borehole usually provides a practical solution to the need to install seismic sensors at depth.

A borehole also creates a very stable operating environment for sensitive instruments. Temperature at depth is very stable and the pressure in a cased, sealed borehole is also very constant. Temperature changes and pressure variations with spectral content within the passband of the sensor system are common sources of nonseismic noise in broadband seismic sensors. Systems installed on the surface or in shallow vaults require extensive thermal insulation systems to reduce the influences of temperature to acceptable levels. Similarly, elaborately designed pressure containers are required to eliminate pressure-induced noise in vertical instruments installed near the surface. A sealed borehole of only moderate depth provides excellent temperature stability because of the tremendous thermal mass and inertia of the surrounding Earth. Similarly, most seismic boreholes are lined with steel casing having cylindrical walls that are quite thick. The casing constitutes a quite rigid container and greatly reduces atmospheric pressure variations within the borehole (assuming that both the top and bottom are sealed).

Boreholes are frequently considered to be expensive, but they often represent the only practical alternative if a ready-made abandoned mine is not available. In many cases, a borehole may actually be the cheapest method for achieving an installation at depth.

It is impossible to state exactly how much it will cost to construct either a borehole or a tunnel-type vault because many variable factors are involved. Precise costs will depend on the type of material in which the facility is constructed, raw material costs, local labor costs, and so on. However, we can give some examples of approximate costs that have been encountered in constructing facilities for the IRIS/USGS GSN

program over the past 5 to 10 y. In Africa IRIS has excavated three drift-type seismic vaults that extended 25–40 m horizontally into hillsides. The costs of these three projects ranged from approximately \$150 000 to \$250 000. For a typical borehole (100 m deep), costs range from approximately \$25 000 to \$200 000 at large landmass sites. On the other hand, at small isolated Pacific Ocean island sites, borehole costs run in the \$150 000 to \$250 000 range.

3.1 Noise Attenuation with Depth

The primary reason for installing broadband sensors in boreholes is to reduce the long-period tilt noise that plagues horizontal sensors that are installed on the surface. The question commonly asked by seismologists who are contemplating a borehole installation is “How fast does tilt noise decrease with depth?” How deep does the borehole need to be? There is no hard and fast easy answer to this question because the borehole never eliminates all of the long-period tilt noise, regardless of how deep the hole is drilled. In general the noise attenuation rate (dB per unit depth) decreases as the depth increases; therefore, most of the noise reduction occurs in the upper parts of the borehole.

As a simplified illustration of noise attenuation with depth, Figure 2 contains relative power spectral density (PSD) noise level data obtained from the simultaneous deployment of four broadband sensors located near one another at the same site and installed at various depths. The first sensor was installed in a small vault on or near the surface. A second sensor was installed in a very shallow borehole only 4.3 m below the surface. The third sensor was installed in a much deeper borehole 89 m down and the fourth seismometer was 152 m below the surface. The site consisted of about 18 m of unconsolidated (soft/weathered) overburden overlying fractured Precambrian granite bedrock. In Figure 2, noise attenuation data points in dB relative to the noise level in the surface sensor are plotted for 30, 100, and 1000 sec to illustrate how much noise power at depth was reduced as compared to the surface installation. Note the very rapid decay in the noise level over the first few tens of meters followed by the much slower rate of decrease in noise levels at deeper depths. Note that in general, a depth of 100 m is sufficient to achieve most of the practicable reduction of long-period noise.

The data in Figure 2 should be regarded as a singular example of noise attenuation with depth. Apparent surface noise levels at a particular site are frequently highly dependent on the methods used to install the instrumentation. This is particularly true of noise levels at many surface site installations where faulty installation of broadband horizontal sensors causes excessive tilt noise at long periods.

Choosing the optimum depth of a borehole for a particular site involves comparing the cost of a borehole of a given depth against the desired data quality requirements, the anticipated surface noise levels (they are frequently determined by the

FIGURE 2 Horizontal surface noise attenuation as a function of depth at three selected periods. The depths were 0, 4.3, 89, and 152 m.

anticipated wind speeds and wind persistence at the site), and the depth of the overburden at the site. Unfortunately, studies detailed enough to yield the precise interrelationship between the various factors have never been conducted. Therefore, choosing the depth of a borehole for a particular site usually involves a healthy dose of “sound engineering guesstimate” based on nonquantitative consideration of the various factors involved. Experience over many years has demonstrated that 100 m deep boreholes drilled at sites with a few tens of meters of overburden overlying relatively competent bedrock will provide a sufficiently quiet environment for installing a high-quality borehole instrument. Most broadband IRIS borehole instruments are installed at or near 100 m depth. Sites with excessive overburden and/or softer, lower-quality bedrock are sometimes deeper depending on construction costs and anticipated surface noise levels.

3.2 Site Selection Criteria

There are several criteria for selecting a site for a borehole installation. Ideally, one should select a site at which the seismic background over the band of interest as measured with a sensor system installed on the surface is as low as possible. However, there are other factors, such as better accessibility, availability of power, improved network configuration, the presence of widespread, thick alluvial fill, and/or the presence of cultural activity within the monitored area, that may force the choice of a site with higher background levels.

A good borehole should penetrate well into bedrock (70–100 m); therefore, the site should have bedrock at or near the surface to minimize the need to drill through excessive overburden. If possible, the bedrock should be a relatively hard rock such as granite or quartzite. Relatively soft rocks such as shale, mudstone, or low-grade limestone should be avoided if possible. Harder, more competent rock increases the rate of attenuation of surface noise with depth and it also decreases the chances of collapse problems during drilling operations.

Good bedrock is highly desirable for providing the ultimate benefit from a borehole, but it is not an absolute necessity for achieving benefits from a borehole site. Note that the first data point in Figure 2 (only 4 m down) was obtained in a very shallow borehole that was drilled entirely in loose alluvial fill. Therefore, the lack of shallow bedrock should not preclude the consideration of a borehole installation for a particular site.

Finally, a reliable source of electricity is necessary to power the site. A shelter is needed to house the recording equipment along with some form of communication capability (telephone line, Internet connection, or RF or satellite link). Accessibility for both the drilling equipment and maintenance personnel should also be considered during site selection activities.

Unfortunately, the need to be able to provide adequate security is also becoming a major factor in selecting station sites in many parts of the modern world. There is little point in investing in a good site if it can not be protected from vandalism. Adequate security has many different meanings depending on the particular situation. It may be as simple as a passive protective fence or as elaborate as alarmed fences and entryways with an on-site caretaker depending on the anticipated level of potential damage.

It should be noted that *very* small islands (such as most coral atolls) are not desirable sites for borehole installations because the ground motion generated by ocean wave loading of the beach penetrates rather deeply into the subsurface environment. Likewise, borehole sites should be an adequate distance (at least several kilometers) from any nearby coastlines (Agnew and Berger, 1978).

3.3 Contracting

Seismic boreholes are usually constructed by local private drilling contractors who follow the specifications supplied by the contracting organization. Hiring a local driller helps reduce the mobilization and setup charges that are frequently a significant portion of the cost of a seismic borehole. Specifications should be rigid and specific enough to assure that the final product will be suitable for borehole seismology and yet flexible enough to prevent excessive costs. It is recommended that the contracting agency hire an independent expert with extensive drilling and casing experience whose duties include on-site observation and supervision of all drilling and casing operations. This precaution is advisable to assure that the drilling contractor performs all operations according to the prescribed specifications, because departures from specifications are hard to detect, document, and prove after the project is finished. The contract should be specific about who is responsible for unexpected difficulties that might arise during the drilling and casing operations. The courses of action should be specified if operations are delayed for any reason whatsoever, including weather, availability of materials or crew, and other circumstances beyond the driller's control.

3.4 Suggested Borehole Specifications

The drilling specifications for a seismic borehole should be written in such a manner as to assure that the completed borehole will be suitable for acquiring high-quality earth motion data. Important parameters such as borehole verticality, depth, diameter, and casing type must be clearly specified. For complete drilling and cementing specifications suitable for soliciting bids, go to "ASL Publications" on the USGS Albuquerque Seismological Laboratory's web site at <http://aslwww.cr.usgs.gov/> and look for "Specifications for Seismic Instrumentation Boreholes."

3.5 Instrument Installation Techniques

It is a relatively simple operation to install a borehole sensor, but certain precautions are in order. The sensors are usually fitted with two cables. The first cable is intended to provide sufficient strength to lift the weight of the sensor and also provide any extra pulling force for removing the sensor from the borehole. This cable is usually a steel cable or "wire rope." The second cable contains the electrical connections for power, control of the various mechanical operations within the sensor, and transmitting the seismic signals back up the borehole. Normally, for holes of significant depth, a small, lightweight electrically driven winch and mast assembly is utilized to lower the sensor into the hole and to retrieve it if necessary. Lowering and raising the sensor should be done fairly slowly because the sensor packages sometimes catch on the casing pipe joints as the package moves up or down the borehole. On the way down, this problem is usually temporary, when it results in a short free fall of the sensor and a sudden stop when the load bearing cable becomes taut again. If severe enough, the sudden stop can damage the sensitive instrument. If the sensor catches on a pipe joint on the way up, tension in the load-bearing cable rapidly increases to dangerous levels if the winch is not stopped in time. If the sensor disengages from the pipe joint while the lifting cable is under high tension, the sensor will undergo possibly damaging levels of acceleration. If the sensor does not disengage and if the winch is powerful enough, the lifting cable may break, thereby endangering personnel in the area.

Traditionally, borehole seismometers are rigidly clamped to the inside of the cased borehole with manufacturer-supplied mechanical hardware to assure adequate coupling between the sensor and ground motion. This hardware usually includes a mechanically driven locking mechanism for clamping the sensor to the walls of the borehole. This device sometimes consists of a motor-driven or spring-loaded pawl that is extended on command from the side of the sensor package to contact the borehole wall opposite from the sensor (Geotech GS-21, Guralp CMG-3TB). Sometimes this function is performed by a separate piece of hardware known as a "hole lock" that is clamped into the borehole on which the sensor package is subsequently rested (Geotech KS-36000,

KS-54000, and earlier Guralp sensors). Mechanical clamping mechanisms have been used successfully for many years and have produced satisfactory data from many installations.

Borehole installations that utilize hole locks have almost always produced more long-period noise in the horizontal components than in the vertical component. In some of these installations, the horizontals were orders of magnitude noisier at long periods than the vertical. The source of the excess noise in the horizontal components has been difficult to isolate and eliminate. For many years, workers in this field have suspected that some of this noise was somehow generated by air motion in the vicinity of the sensor package. The conventionally designed (this includes all sensors with garden gate type of suspension such as the STS-1, CMG-3 series, KS-36000, and KS-54000) horizontal components of long-period seismometers are extremely sensitive to tilt. This is due to their inability to separate the influences of pure horizontal acceleration input to the sensor frame (the desired input) from the signal that arises from the tilting of the sensor package (tilt noise). Therefore, fairly elaborate schemes for reducing the potential for air motion around the sensor within the borehole have been devised and utilized with varying degrees of success. Through the process of trial-and-error development, it has become customary to wrap the sensor package (KS-36000s and KS-54000s) with a thin layer of foam insulation in an attempt to somehow modify the flow of heat near the seismometer in the borehole. In addition, it has become common to place long plastic foam borehole plugs immediately above these sensor packages deep in the borehole and near the top of the borehole to block air motion in these sections of the borehole. Additional insulation, which is intended to further reduce air motion within the borehole, is sometimes employed near the top of the sensor package.

Recently, a highly successful method for significantly reducing the long-period noise levels in borehole installed horizontal components has been developed at the Albuquerque Seismological Laboratory. For a complete report on this technique, go to "ASL Publications" on the USGS Albuquerque Seismological Laboratory's web site at <http://aslwww.cr.usgs.gov/> and look for "Experimental Investigations Regarding the Use of Sand as an Inhibitor of Air convection in Deep Seismic Boreholes," USGS Open File Report 98-362.

Determining the orientation of the horizontal components of a seismometer installed in a deep borehole is not a simple matter because one cannot physically get at the instrument once it is installed. One must resort to indirect methods for determining how the instrument is oriented in the hole. For a complete report on this technique, go to "ASL Publications" on the USGS Albuquerque Seismological Laboratory's web site at <http://aslwww.cr.usgs.gov/> and look for "Experiments in Seismometer Azimuth Determination by Comparing the Sensor Signal Outputs with the Signal Output of an Oriented Sensor."

3.6 Typical Borehole Parameters

There are now many broadband borehole installations in use throughout the world. Most of these boreholes are geometrically quite similar because they were designed to accommodate the same type of seismic instruments. All of these boreholes are approximately 16.5 cm in diameter and most of them are drilled to a maximum of a 3.5° departure from true vertical (the borehole at JOHN is rather crooked—5.5° from vertical). They are all cased with standard oilfield grade casing and most of them are watertight.

There is some variation in the depths of these boreholes. As mentioned earlier, the vast majority of these boreholes are approximately 100 m deep. However, some of these boreholes are considerably deeper if they were drilled in areas with thick overburden or poor bedrock. For instance, the borehole sensor at DWPF (Florida) is installed at a 162 m depth because the overburden at DWPF is approximately 46 m thick and the upper layers of bedrock consist of interleaved units of varying grades of soft limestone. The borehole at ANTO, which is drilled in competent rock for most of its depth, is the deepest and oldest IRIS borehole at 195 m. This was the first field borehole that was drilled for the SRO program: As more experience was gained, it became apparent that boreholes that deep were not cost-effective installations. A few of the boreholes are shallower, primarily because severe difficulties were encountered during the drilling operations that necessitated finishing the borehole at a shallower depth than originally desired. For example, the sensor at JOHN is only 39 m down because severe cave-in conditions were encountered during the attempt to drill deeper. Johnson Island is a coral atoll and the surface layers are very poorly consolidated; true bedrock probably lies at very great depths. Drilling in volcanic regions often proves to be very difficult. The borehole at POHA was terminated at 88 m because the drillers experienced severe "loss of circulation" conditions throughout the drilling operation. The surface layers at POHA on the island of Hawaii consisted of badly fractured weathered basalt layers and basalt rubble separate by scoria rubble, ash flows, sand, and other assorted debris produced by an active volcano. Drilling conditions in the volcanic deposits on Macquarie Island proved to be so difficult that it was impossible to complete a borehole.

3.7 Commercial Sources of Borehole Instruments

Currently, there are only two known commercial sources of high-sensitivity, broadband, borehole-installable seismometers. For many years, Teledyne Geotech (renamed Geotech Instruments LLC (www.geoinstr.com)) in Dallas, Texas, USA, was the only source of high-sensitivity instruments (KS-36000, KS-54000, GS-21, and 20171) designed specifically for borehole installations. Both the KS-36000 and the KS-54000 are three-component broadband closed-loop force feedback sensors that

are designed for deep (up to 300 m) borehole installations. The GS-21 is a conventionally designed short-period, vertical instrument intended for superior high-frequency performance in deep boreholes. The 20171 is a slightly noisier and slightly cheaper version of the GS-21. The KS-36000 is no longer manufactured, but there are many of these instruments still in operation in boreholes around the world. Geotech plans to have a new sensor ready for market sometime during 1999; it will be denoted the KS-2000 and it will be available in both surface and borehole installed versions.

For the past four years or so, Guralp Systems Ltd., Reading, UK (www.guralp.demon.co.uk) has been producing a borehole version of the CMG-3T (referred to by some as a CMG-3TB). This instrument is much smaller and lighter than is a KS sensor. The CMG-3TB is also considerably less expensive than a KS sensor. This sensor is a three-component, broadband, closed-loop, force feedback instrument that is very easy to install. Guralp Systems has recently introduced a new borehole sensor that has both velocity and acceleration output and is integrated with its own digitizer. In addition, they are willing to work with the customer to meet specific requirements.

A borehole version of the Streckeisen STS-2 has been under development for several years. Currently, a basic prototype of the instrument exists, but the instrument requires further development of the remote control functions and the final packaging design is yet to be determined. Streckeisen has not announced an availability date for the new instrument.

It is somewhat hazardous to quote sensor prices because they are continuously subject to change by the manufacturer and international currency exchange rates change daily, but the following are some approximate current relative costs for borehole sensors in 1999 US dollars. These prices should be viewed as being approximate; potential buyers should consult the manufacturer for a current quotation.

A Geotech KS-54000 by itself is priced at nearly \$65 000 with added cost (about \$40 000 for a conventional installation or about \$13 000 if installed in sand) if all of the associated installation hardware is purchased. However, this price may be reduced if the instruments are ordered in sufficient quantities (25 or more). A GS-21 is priced at about \$8000 and the 20171 weighs in at around \$6000 for the instruments themselves. The associated hardware (soft electrical cable, wire rope, winch, etc.) is additional. Estimated delivery time for these instruments is 120 days or more after receipt of order depending on the availability of non-Geotech-manufactured parts. The KS-2000 sensor to be introduced soon will be priced at below \$10 000 for the surface system and the borehole version will probably be well below \$20 000.

A Guralp Systems CMG-3TB costs about \$28 000 if the instrument is to be installed in sand. A hole lock-equipped version is about \$39 000. Currently delivery time is about 9 months; however, the manufacturer is trying to decrease delivery time to about 6 months.

3.8 Instrument Noise

It is important to remember that the purpose of installing seismic instrumentation in boreholes is to obtain quiet seismic data. This intent will be foiled if the seismic sensor system itself is too noisy to resolve the lower levels of earth background noise that are expected to be found at the bottom of the borehole. As delivered from the factory, sensor self-noise levels sometimes vary over a wide range and some instruments may be far too noisy to operate successfully in a quiet borehole. It is therefore recommended that the self-noise of all borehole instruments be measured before installation in the field to assure that they will be quiet enough to be able to resolve the background levels of earth motion anticipated at the bottom of the borehole. Self-noise measurements are usually made by installing two or more sensors physically close enough together to assure that the ground motion input to all of the sensors is identical. The data produced by the sensors is then analyzed to determine the level of the incoherent power in each sensor's output. This incoherent power is usually interpreted as the sensor internal noise level. To achieve high-fidelity recording of true ground motion, the seismometer system self-noise level should be well below the anticipated background earth motion levels across the band of interest at the site.

The low-noise models in Figure 3 can serve as guide lines to the instrument noise levels that may be expected from the CMG-3TB and the KS-54000 sensor systems. In this figure, the CMG-3TB low-noise model (CMGLNM) is the longer-dashed line and the KS-54000 low-noise model (KSLNM) is the shorter-dashed line. The solid heavy line in the figure is Peterson's (1993) new low-noise model (NLNM) for the earth background noise at a quiet site. The reader should recognize that there is no single known site in the world whose background power spectral density levels reach NLNM levels across the entire band. Instead, the NLNM is a composite of the lowest earth noise levels obtained from many sites. Similarly, the low-noise models for the instruments should not be regarded as being typical of all instruments, because each seismic sensor has a distinct "personality" of its own. Instead, the low-noise models for the instruments should be regarded as lower limits of instrument noise, just as is the case for the NLNM of earth noise. Individual instruments will in all probability be noisier than the low-noise model for that instrument over at least portions of the spectrum.

The CMGLNM plot in Figure 3 is based on a composite of experimental test data obtained at the Albuquerque Seismological Laboratory over a period of several years. The central portion (from about 0.6 to about 20 sec) of the model was not actually measured because of numerical resolution limits of the current data processing algorithms. This portion of the model is an estimate. As a general rule, many CMG-3TB instrument noise levels approach the CMGLNM at short periods (less than 0.6 sec), while fewer of these instruments achieve the indicated noise levels at long periods (greater than 20 sec).

FIGURE 3 Low-noise models for the KS-54000 (KSLNM) and the CMG-3TB (CMGLNM) sensor system self-noise relative to Peterson's (1993) New Low-Noise Model (NLNM) for background earth motion.

The KSLNM plot in Figure 3 is a factory-derived theoretical instrument noise level. As such, it should be regarded as an optimistic estimate of the lower limits of the self-noise in the KS-54000. Most KS-54000 real-world instruments are probably noisier than the levels indicated by the KSLNM curve.

4. Seismic Installations in Tunnels

For many years, abandoned mines have been used as ready-made quiet sites for installing seismic instrumentation. In some cases, even though the site may be somewhat noisy as a result of mining activity during the workday, active mine tunnels have also proved to be successful facilities for seismic stations.

Existing tunnels in solid rock provide very low-cost ready-made facilities that often have convenient existing access and nearly ideal conditions for the installation and operation of high-sensitivity seismic sensors. The bedrock in a mine tunnel is usually already exposed, thereby providing an excellent firm foundation on which to install standard surface instruments. If unventilated, as is usually the case for abandoned mines, a mine tunnel provides an essentially constant-temperature environment that is ideal for seismic sensors. Depending on its thickness, the overburden above the mine tunnels provides varying degrees of isolation of the seismic sensors from the seismic noise that is always present at the surface of the Earth.

Mines are usually geographically located in mineralized zones. Therefore, it is unlikely that an existing mine will be found near the location of many proposed seismic installations. As a result, tunnels are sometimes constructed solely for the purpose of the installation of seismic sensors. Digging tunnels in hard rock without the benefit of a cost-offsetting by-product such as a marketable mineral-bearing ore is a very expensive endeavor.

In many respects, a tunnel installation is quite similar to a surface vault installation. A poured concrete floor or pier is usually constructed on the rough bedrock floor of the tunnel to provide a flat and relatively level surface on which to install the sensors. Despite the improved temperature stability, it is still necessary to provide adequate thermal insulation around the sensors in order to reduce thermally generated noise. A system to reduce the variation in air pressure is also necessary for long-period sensors in underground tunnels. Usually this is accomplished in the same manner as in a surface installation, although sometimes an effort is made to seal off all or parts of the tunnel itself. Sealing a volume enclosed by natural rock walls is difficult because most tunnel walls are riddled with fractures.

In other respects, there are significant differences between surface vault installations and tunnel sites. One of immediate concern is the danger of rock fall in a tunnel installation. Another concern is the danger of the build-up of harmful

gasses (bad air) underground if the tunnel is not adequately ventilated.

A common problem in many tunnel installations is the presence of water and high humidity levels in most underground passages. It is very difficult to keep the instrumentation dry, and the wet environment is frequently very unpleasant to work in. The high humidity slowly corrodes the contacts in delicate electrical connectors, which frequently causes poor electrical contact and intermittent operation. The presence of moisture also slowly degrades the effectiveness of thermal insulation materials; therefore, precautions must be taken to prevent moisture accumulation in the thermal isolation system.

Access to power and communications lines is usually more difficult in tunnel installations depending on how far into the tunnel one chooses to position the equipment. Frequently, power and/or communication lines must be installed throughout the entire length of the tunnel. Power can be quite expensive to supply if long distances are involved. Either large-diameter power conductors must be used or a high-voltage line coupled with a step-down transformer must be installed to assure that sufficient voltage is available at the site.

Determining a sensor orientation azimuth line underground is considerably more difficult than in a surface installation. Usually, one must transfer an already known azimuth from outside the tunnel to the installation site within the tunnel using standard land surveying techniques. There are specially designed gyroscopically based systems that can determine the orientation underground, but they are rather expensive.

If a time reference source is required for the installation, it can be difficult to provide this source to a tunnel site. Modern GPS-based timing systems require a relatively short cable between the above-ground antenna and the below-ground receiver. If the tunnel installation is too deep, an in-line radiofrequency amplifier may be required.

5. Future Directions

5.1 Global Seismograph Stations as Geophysical Observatories

There are a number of nonseismic geophysical measurements that are of scientific interest. Some of these, such as temperature, barometric pressure, and wind, may affect the seismic measurements themselves. Others may not have a direct effect on local ground motion but may be of long-term observational interest anyway. Since global seismic observatories typically have a long lifetime at a given site, it makes sense to take advantage of the siting and infrastructure at these observatories and to make long-term observations of any and all geophysical parameters that may be of interest to researchers in other fields. This results in the observatory appealing to a wide range of interests and to concomitant long-term support.

5.1.1 Meteorological Observations

- Temperature measurements are of widespread scientific interest. Temperature can affect seismometer mass positions in shallow installations. Temperature variations may also affect digitizer offsets and noise levels, as well as tape recorders and fixed disks in the seismic data acquisition systems.
- Both absolute pressure measurements and pressure variations are of interest to the meteorological and seismic communities. Absolute pressure measurements give a measure of the total mass of the atmospheric column above the seismic station. These can be used to correct the gravitational attraction of the atmosphere on the mass of the vertical seismometer, resulting in lower vertical seismic noise levels in the long-period band. Variations in atmospheric pressure, especially those caused by wind, are a prime cause of local tilting of the ground surface (attenuating with depth), resulting in increased horizontal seismic noise levels in the long-period band. This is because a typical inertial horizontal seismometer cannot distinguish between tilt and horizontal acceleration. Therefore, recordings of atmospheric pressure variations have potential use in removing some of this tilt noise from the horizontal seismic data.
- Wind velocity (speed + direction) is also of interest to the meteorological and seismic communities. The wind has a strong effect on seismic noise levels, especially in shallow installations. (See also discussion on pressure variations above.)
- Relative humidity is of interest to the meteorological community. When relative humidity is used in conjunction with absolute pressure and GPS information, a measure of precipitable water vapor may be obtained.

5.1.2 Other Geophysical Observations

- Rapid changes in the intensity and/or declination of the Earth's magnetic field are of interest to the geomagnetic community as well as to seismologists. Magnetic storms can affect modern broadband seismometers if they are not magnetically shielded, especially vertical seismometers. (The spring suspending the mass is especially affected.) Example: The borehole seismometer installed at station COLA (College Geophysical Observatory) is installed in a PVC casing rather than the usual steel casing that provides magnetic shielding. At this high latitude (Alaska), magnetic storms are especially intense, and the effects from them can occasionally be seen in the vertical broadband data from this instrument, at periods longer than 30 sec.
- Measurements of the absolute intensity and declination of the magnetic field are much more difficult, because it is necessary to install the magnetometers in a magnetically clean environment (no steel or iron in the area, for

example). Most seismometer installations use a lot of steel or iron: Most borehole casings are steel and most normal buildings have steel or iron in them (nails, reinforcing bars, etc.). However, it may be convenient to colocate magnetic observatories with seismic observatories if care is used in relative placement of instruments and in the materials used (as in the case of College Geophysical Observatory, Alaska).

- Geodetic GPS measurements have become quite important to seismologists as well as to those responsible for accurate location of GPS reference sites, precise determination of GPS orbits, and a host of other considerations. Of special interest to seismologists is the determination of the velocity vectors for the Earth's tectonic plates and the measurement of strain accumulation near major fault systems. In addition, real-time GPS information may be used by meteorologists in conjunction with temperature and relative humidity (see meteorological discussions above).

It may be impossible to specify a complete list of possible long-term observations one could or should make at seismological observatories. However, there are some interesting possibilities, given the semipermanent nature of the established infrastructure at a global seismological observatory:

- Luminous phenomena (LP): possible association with earthquakes
- Electromagnetic phenomena (VLF, RF, etc.): possible earthquake precursory signals
- Strain (both volumetric and linear)
- Tilt (pure rotational measurement)

5.2 Global Communication Systems

Historically, it has not been cost-effective to telemeter seismic data to Data Collection Centers in real time, because expensive dedicated circuits were necessary. The cost of such international circuits can be as much as \$20 000 per month, per station. However, since the early 1990s, the Internet has become almost ubiquitous. It has become possible to use the Internet to telemeter data in near real time for the minimal cost (tens to hundreds of dollars per month) of a "tail circuit" from the nearest Internet Service Provider (ISP) to the seismic station. The downside of using a link like the Internet is intermittent outages, so it is necessary to use a re-transmission protocol to fill in data gaps on the receiving end. Dedicated circuits are still necessary when the data *must* arrive within seconds.

Another relatively inexpensive development in the late 1990s is international VSAT satellite link capability. For an equipment investment of about \$50 000, one can obtain 19.2 kbps full duplex service for about \$200 per month (depending on country tariffs and the satellite used). Further advances may make satellite internet communications as inexpensive as any of the current commercial satellite TV connections.

5.3 Instrumentation Improvements Needed

5.3.1 Bandwidth and Dynamic Range

Since the analog-recording days of the WWSSN, available bandwidth has increased from 2 decades (0.01 to 1 Hz) to 8 decades (10^{-6} to 100 Hz) for a fully capable GSN or equivalent very broadband station. Also, dynamic range has increased from 40 dB to 140 dB (or more, at very low frequencies).

However, earthquake amplitudes span a range in excess of 240 dB (lowest peak earth acceleration at 400 sec period to maximum acceleration very near the epicenter of a large earthquake). Frequency ranges of seismological interest are mostly covered with the above 8-decade range, but one can argue for an even larger frequency range, depending on the application. Perhaps 10^{-8} to 10^3 Hz is sufficient for practically all foreseeable seismological applications.

With current (2002) technology, it is necessary to use more than one instrument to cover all frequency and amplitude ranges of interest. The situation is much better than it was historically (for example, the prefiltered, oversensitive recording used in the SRO). However, just as was required in using SRO data, one must still patch together waveforms from different instruments in order to derive a complete time history of ground motion from a great earthquake at all distances from epicentral to teleseismic. The ideal way to rectify this situation is to build a single system (seismometer plus acquisition system) that is capable of covering the entire bandwidth and dynamic range requirement *in a single data stream*.

Although this is obviously not an easy task, it should be the ultimate goal. This goal translates into the following nominal system specifications:

- Dynamic range: 250 dB (corresponds to a 42-bit digitizer)
- Noise level: equal to or smaller than -220 dB relative to 1 m sec^{-2} peak-to-peak
- Clip level: at least 39.2 m sec^{-2} (4 g) peak-to-peak
- Frequency range: 10^{-8} to 1000 Hz

5.3.2 Noise Reduction

Installation techniques are always subject to improvement as instrumentation improves (see previous discussion on installation practices). As instrument noise levels decrease, frequency bands increase, and instrument sizes shrink, better installation techniques will become both necessary and more feasible. For example, the development of a high dynamic range "seismometer on a chip" would make it possible to drill very small (perhaps 2 cm diameter) boreholes instead of the 18–25 cm boreholes currently needed. This would make it possible to drill the holes much deeper in order to achieve greater attenuation of surface-generated noise. In addition, verticality requirements, currently typically specified at less than $3\text{--}5^\circ$ because of instrument leveling limitations, should be greatly eased in new seismometers having a very large dynamic range.

Very inexpensive, very small, high dynamic range seismometers should also make possible the easy deployment of massive “arrays” of seismometers. This should, in turn, make possible the use of noise-reducing array signal processing techniques on data from very large numbers of observatory-quality global seismic stations.

5.3.3 New Instruments Needed

- Seismometers capable of 250 dB dynamic range (noise levels less than the USGS New Low Noise Model, clip levels of 2 g peak).
- Digitizers capable of 250 dB dynamic range at 2000 samples per sec (42-bit).
- Pure tilt (rotational) meters with noise levels less than 10^{-12} radians over a 0.0001 to 1 Hz range. Such instruments can be used to remove the noise contamination in horizontal accelerometers (inertial seismometers) caused by tilt noise at or near the Earth’s surface, as well as to separate the rotational component of surface waves from the translational component.
- Clocks that do not need an antenna, with absolute accuracy of 1 μ sec and drift rate less than 1 μ sec per 10 y of operation.
- On-site recording should be on solid-state nonvolatile media with no moving parts, with enough capacity to contain at least one year of data.
- Telemetry of all data from acquisition system should work from any position on Earth (perhaps through LEO satellite systems).
- All of the above should have extremely low power consumption, so that the entire system will operate for at least one year between battery changes or battery charges. Complete seismic station systems consuming higher amounts of power will require connection to reliable commercial power or a very robust backup power system.

The Structure and Interpretation of Seismograms

Ota Kulhánek

Uppsala University, Uppsala, Sweden

1. Introduction

Interpretation of seismograms is devoted to the art of identification of various types of seismic waves (phases) that appear on seismograms and often generate a rather complex structure. Correct identification of recorded phases with respect to travel paths through the Earth is the doorway to any research using observational seismic data. The appearance of a seismogram reflects the combined effects of the source, the path of propagation, the characteristics of the seismograph, and the ambient noise at the recording site. Understanding the complicated nature of seismograms requires knowledge of seismic source physics, the structure of the Earth, and seismic wave propagation. Above all, it requires long experience in examining seismograms. A veteran seismogram analyst frequently reveals and correctly interprets record features invisible to novice interpreters, recalling Emil Wiechert's "... jede Zacke, jede Zunge zu erklären..." ("every jerk, every wiggle should be explained"). An experienced analyst will usually be able to decipher even complicated records merely by visual inspection. It is, however, desirable to confirm the interpretation by using the proper travel-time tables and synthetic seismograms.

If the studied earthquake exceeds a certain magnitude, its seismic waves can be recorded by seismographs located at places everywhere in the world, on the surface of the Earth, in boreholes or abandoned mines, or on the ocean bottom. Generally speaking, at increasing distance from the epicenter the wave amplitudes diminish due to anelastic attenuation (rocks are not perfectly elastic), geometrical spreading (the area of the wave front increases with increasing propagated distance), and energy loss at interfaces (reflection, refraction, mode conversion, diffraction, scatter). The anelastic attenuation is frequency-dependent (high frequencies are subject to high attenuation) so that high-frequency seismic signals attenuate rapidly and may be recorded only by proper seismic instruments placed at relatively short epicentral distances.

Due to the internal structure of the Earth, at certain distances, e.g., around 20° and 144° , concentration (focusing) of the energy of traveling seismic waves takes place. Seismic signals recorded close to these distances often show an increase of amplitude even with increasing distance from the epicenter.

Source radiation is another factor that influences the amplitude of arriving seismic waves. Tectonic earthquakes, in contrast to underground explosions, cannot be treated as spherically symmetric point sources because the radiated seismic energy transported by certain wave types is beamed in certain directions. It is therefore likely that seismographs deployed at different azimuths will show different amplitude ratios between arriving P and S waves.

The plot in Figure 1 illustrates some of the basic properties of recorded body and surface waves. There is a sharp P onset, followed after approximately $4\frac{1}{2}$ min by a clear S onset. About 2 min after the S arrival, we observe a gradual increase of the amplitude due to the arriving surface wave of Rayleigh type, LR (vertical-component seismogram). At the beginning of the LR wave, the wave period is about 40 sec, but it decreases to about 25 sec after three or four swings, clearly demonstrating the dispersive character of the LR wave, which in this case manifests a continental propagation path signature. Furthermore, the LR wave is the largest signal in the seismogram, indicating that the earthquake occurred at relatively shallow depth.

Since various seismic phases propagate with different velocities along different paths, they arrive at the recording site well separated in time. Theoretically, therefore, there should be no difficulty in recognizing these phases in seismograms. Indeed, in this particular case (Fig. 1, chosen for didactic reasons), the noise level (cf. the portion of the record preceding the P onset) is very low when compared with amplitudes of the recorded P or S waves. Here, the decay of P wave amplitudes, so called P -coda, is rather rapid so that

not only the P onset but also the S onset can easily be identified. However, it is more common that the analyst has to examine records with high background noise and to identify various wave arrivals masked by noise and/or onsets due to other events (Fig. 2), which often is a difficult task. Note also that, except for the first P onset, all further arrivals are obscured by coda of preceding phases, so that on the seismogram there is virtually no interval of quiescence between individually arriving phases.

To complicate the matter further, seismic waves encountering a discontinuity are reflected and/or refracted and an incident P or S wave gives rise to both P and S waves, so-called mode conversion. Thus seismograms often show a large number of distinct phases, distributed in time, which have

FIGURE 1 Seismogram made at Uppsala, Sweden, by a long-period, vertical-component instrument. This earthquake occurred on Crete, Greece, on 12 June 1969 ($M = 6.2$, $h = 25$ km) at a distance of 26° from Uppsala. The onset of P is distinct. The S wave arrives about $4\frac{1}{2}$ min after P and is also easily recognizable. The trace also shows a clear dispersive Rayleigh wave train, starting 2–3 min after S . The sudden increase of LR -wave amplitude starting approximately 6–7 min after S is due to the arriving Airy phase. Time advances from left to right and there is 1 min between successive time marks (small upward offsets). (Reprinted with modifications from Kulháněk (1990) with permission from Elsevier Science.)

traveled along different propagation paths and which have been subjected to different mode conversions P -to- S or S -to- P .

The ground is practically always in motion. Various human activities such as traffic, construction work, industrial activity, etc. generate so-called cultural noise with dominant frequencies usually above 1 Hz. A similar type of noise is also generated by the action of wind, smaller water basins or rivers, and so on. Various interactions between atmospheric effects, oceans, and the solid Earth give rise to microseismic noise, sometimes also called ocean microseisms. The dominant frequencies of microseisms occupy a broad low-frequency range from less than 0.01 Hz to, say, 0.5 Hz, that is, periods from 2 sec to more than 100 sec. The most common microseisms have more or less regular periods of about 6 sec. Cultural noise is recorded with standard instruments at epicentral distances usually not exceeding several tens of kilometers and is, therefore, only of local importance. Microseisms, on the other hand, can travel hundreds of kilometers and, hence, are a continental phenomenon.

2. Seismogram Characteristics

In the sections that follow, we will focus the presentation on seismograms from tectonic earthquakes. For the sake of comparison, several examples from volcanic earthquakes and from unusual seismic sources will also be included.

Let us start with a brief summary of the most important characteristics of seismic waves that deserve our attention and that are invaluable in any seismogram interpretation. First, different waves travel with different velocities. At any epicentral distance, P is recorded first, followed by S , LQ (Love wave) and LR (Rayleigh wave). Second, different waves are polarized in different ways (P linearly, LR elliptically). This provides a means of identifying phase types. Third, various phases are characterized by their amplitude, period, dispersion, etc.

FIGURE 2 Seismogram made at Kiruna, Sweden, by a short-period, vertical-component seismograph. The earthquake occurred in Kuril Islands on 7 May 1996 ($M = 5.7$, $h = 52$ km) at an epicentral distance of 62° . The P wave arrives at 23:30:14.5 and is preceded and to some extent masked by a wave train from an explosion, in a local iron ore mine, which arrives about 14 sec earlier. Both arrivals (arrows) can easily be misinterpreted as onsets belonging to the same event.

The propagation of seismic waves through the Earth's interior is governed by exact physical laws similar to the laws of light waves in optics. In general, the wave velocity increases with depth and, consequently, seismic energy follows rays that are curved with the concave side upward providing the shortest time-path through the Earth. For a spherical Earth, it is common practice to express the distance between the focus and the recorded station as the angle (denoted Δ) subtended at the center of the Earth by the arc between the source and receiver ($1^\circ \approx 111$ km).

In the following discussion, we introduce several categories of seismic events. The classification is based on the distance between the event and the recording site (i.e., on the epicentral distance), which in turn governs propagation paths along which seismic waves travel through the Earth's interior. Another categorization used is that according to focal depth. Earthquakes with focal depth between 0 and 70 km (about 80% of all earthquakes) are shallow-focus earthquakes. Intermediate-focus earthquakes have focal depth between 71 and 300 km. Shocks deeper than 300 km are called deep-focus earthquakes. The main reason for these classifications, which do not provide any sharp line of demarcation, is that seismic waves from the different categories may be discriminated from each other due to their different appearances on seismograms.

There are numerous ways of classifying seismogram on the basis of epicentral distances. We will consider events recorded at distances shorter than about 1° as local events. Regional events are events recorded at distances between approximately 1° and 10° . Local and regional distance seismograms are dominated by seismic energy that has propagated through the crust and/or along the Moho discontinuity. Corresponding

seismic waves are called crustal waves. Seismic waves propagating through the upper mantle are recorded at distances, roughly speaking, between 10° and 30° . P and S waves recorded at these distances are complex due to interactions with the upper-mantle discontinuities. At recording distances from about 30° to 103° , seismic waves propagate through the lower mantle. Corresponding seismograms are relatively simple due to smooth velocity distribution between 700 km depth and the core-mantle boundary (CMB). For epicentral distances larger than about 103° , seismic waves propagate through the core or are diffracted by the core and seismograms again become complicated. Events recorded at distances larger than about 20° (some workers prefer the distance of 30°) are called teleseismic events or simply teleseisms.

2.1 Crustal Waves; Recording Distances 0– 10°

In order to explain the structure of seismic records made at epicentral distances between 0° and 10° , let us first assume a simplified structural model of the crust, depicted in Figure 3. Note that for the distances considered here, we neglect the effects of curvature of the Earth's surface.

Consider waves (rays) leaving the focus F and reaching the recording stations S_1 , S_2 , and S_3 . Since the source radiates both P and S waves, there will be direct longitudinal and transverse waves recorded along the Earth's surface. These waves have ray paths such as FS_2 (see Fig. 3) and are encoded as Pg and Sg or sometimes as $\bar{P}$ and $\bar{S}$. The g indicates the travel path, which for seismic events in the upper crust (most of the crust earthquakes) is entirely confined to the granitic layer. A reflected ray (e.g., ray path FR_1S_1) is also possible from the

FIGURE 3 Principles of wave propagation from the focus of earthquake F through a simplified one-layer crust model. Symbols O and M designate the Earth's free surface and Moho discontinuity, respectively. S_k is the k th recording seismographic station, i is angle of incidence, i_r is angle of reflection, i_c is critical angle, and V is velocity of propagation for P or S . R_k are the points of reflection at the Moho discontinuity for rays that travel to the k th station. (Reprinted from Kulháněk (1990) with permission from Elsevier Science.)

Moho, and the corresponding reflected P and S waves are labeled as PmP and SmS , respectively.

It follows from Figure 3 that, as the epicentral distance increases, the angle of incidence (i) and the angle of refraction (i_r) also increase. At a certain critical epicentral distance, $i_r = 90^\circ$, the energy of the refracted ray does not penetrate into the mantle but travels along the Moho discontinuity (cf. the ray path $FR_2R_3S_3$). The associated angle of incidence, i , called the critical angle, is denoted i_c . Corresponding P and S waves, called head waves, recorded at S_3 are labeled Pn and Sn , respectively. Waves propagating along discontinuities separating two layers with two different velocities propagate with the higher of the two velocities. Thus, Pn and Sn waves depicted in Figure 3 travel with velocities of the uppermost mantle. As can be seen in the figure, Pg and Sg exist for all epicentral distances from $\Delta = 0$ and outwards; whereas Pn and Sn phases cannot be observed at distances shorter than that corresponding to the location of the station S_2 (Fig. 3), i.e., at distances shorter than the critical distance, which for the continental crust is about 100 km.

It should be stressed that in the above presentation and in Figure 3, a number of simplifications have been made. First, a homogeneous crust is in most cases a rather poor approximation of the true structure. It is common to employ two crustal layers, separated by the Conrad discontinuity, to interpret crustal phases. In special studies, multilayered crustal models are used. Second, the true Moho and Conrad discontinuities are not planar and strictly horizontal boundaries. In reality, they dip and have some degree of undulation. Last, the assumption of Pg or Sg traveling as direct waves (P or S) over large distances, as shown in Figure 3, is again a gross simplification. In practice, direct waves, denoted $\bar{P}$ and $\bar{S}$, are recorded only from local events, i.e., at very short epicentral distances usually not exceeding several tens of kilometers. (See Plate 21.1: Note that all plates are placed on the attached Handbook CD, under the directory of \21Kulhanek.) Pg and Sg waves are then understood as channel or refracted waves traveling along less pronounced boundaries within the granitic layer.

Accepting the two-layer model, we realize that, starting from about 100 km, we record additional phases, namely the refracted P and S traveling along the Conrad discontinuity. An asterisk, P^* and S^* , indicates this phase. An alternative code sometimes used is Pb and Sb . The b refers to basaltic layer.

At very short distances, less than 150 km or so, and for a shallow focus in the upper crust, the first wave arriving at the recording station is $\bar{P}$ or Pg , traveling with a velocity of about 6 km sec^{-1} . For distances larger than critical but less than about 150 km, Pg is followed by P^* and subsequently by Pn . P^* and Pn travel with velocities of about 6.6 and 8.0 km sec^{-1} , respectively, i.e., significantly faster than Pg . Therefore, at distances larger than approximately 150 to 200 km (depending upon the true propagation velocities and the thickness of the granitic and basaltic layers), crustal waves change their order of arrival. For distances larger than about

200 km, the first-arriving phase is Pn , P^* arrives next, and then Pg . Obviously, this is true only for continental travel paths. Seismograms from earthquakes beneath the sea bottom, made at island or coastal stations, will not show Pg or Sg phases since there is no granitic layer in the oceanic crust. Similarly, earthquakes originating in the lower crust, beneath the Conrad discontinuity, do not produce Pg or Sg phases. Hence, first arrivals on records from these earthquakes will be Pn or P^* .

For ease of phase identification, rather than relying on the epicentral distance, which of course may not be available, we can make use of time differences between arrivals of various phases. For example, if the arrival-time difference $S-P$ is less than about 20 sec, the first wave within the P and S group to arrive at the recording site is probably Pg (or $\bar{P}$) and Sg (or $\bar{S}$), respectively. If on the other hand, the difference is more than 25 sec, the first arrival is most likely Pn . Details obviously depend upon the true structure and upon the focal depth. It should be emphasized that only seldom are all the above phases identified on one record. The usual case is that one or several of these waves are too weak or hidden in the background noise to be discernible on the seismogram.

With a certain time delay following the P phases, proportional to the epicentral distance, the crust S waves arrive in the same order as P waves. Thus, for local events (earthquakes, mine explosions, quarry blasts, etc.) the order of S onsets will be Sg , S^* , Sn , while for events from distances larger than about 300 km we observe first Sn followed by S^* and Sg .

P or S waves reflected from Moho are rather scarce and difficult to identify. The best chance of recording PmP or SmS is at short distances where the contamination by Pg and Pn (or Sg and Sn) is not severe. Sometimes, so-called depth phases, arriving between Pn and Pg , are present on seismograms. These leave the focus as P waves, travel upward with a small angle of incidence, are reflected as P at the free surface, and continue further as Pn . Notation for this phase is pPn . Similarly, sPn denotes a depth phase leaving the focus as S , converted through the reflection at the free surface and continuing as Pn . Both pPn and sPn are of great importance in focal depth estimations, but at the same time are rather difficult to identify on actual records.

Short-period S waves multiply reflected between the free surface and Moho, or between other crustal velocity discontinuities, interfere with each other and give rise to a wave group labeled Lg , which follows the Sg arrival. The g again refers to granitic layer. At distances of several hundred kilometers and larger (continental paths), Lg waves, propagate as guided waves through the crust, as they supercritically reflect from the Moho and Earth's surface. Lg waves propagate with a typical velocity of about 3.5 km sec^{-1} , and have large amplitudes, especially on the horizontal components. Lg is usually recorded at epicentral distances of about 5° and larger, although there are reports of Lg propagating over distances of several thousand kilometers (Kulháněk, 1990) and being recorded as prominent phases on the seismograms.

Near-surface regional events (earthquakes, industrial explosions, rockbursts, etc.) also generate short-period surface waves of Rayleigh type, labeled *Rg*. The presence of short-period *Rg* in the seismogram is a reliable indicator of a very shallow event with focal depth of the order of one or a few kilometers. On the other hand, if short-period *Rg* waves are absent (near station, epicentral distance of several hundred kilometers or less), we are concerned with a deeper natural event, i.e., with a crustal earthquake at a depth most likely between about 5 and 25 km, since all types of man-made events as well as triggered mine tremors can be excluded. Short-period *Rg* waves, which travel as guided waves through the crust across continental paths with velocity of 3 km sec^{-1} or slightly higher, are attenuated more strongly than crustal body waves and their range of propagation is therefore limited to distances less than about 600 km (Båth, 1983). However, at short epicentral distances, of say, less than 100 or 200 km, the *Rg* phase from a near-surface event often dominates the recorded wave train (Fig. 4).

Seismic waves from local and regional earthquakes of low or moderate magnitude are of short period and are therefore almost exclusively recorded by short-period seismographs. The seismogram duration depends upon the magnitude, but for events with $M < 5$ generally does not exceed 5 min or so. The number of clear pulses seen on the record, indicating arrivals of the whole group of crust *P* and *S* waves, is often larger than one would expect from models displayed in Figure 3, demonstrating the complex structure of the crust. For continental trajectories, the most prominent phase is usually *Sg*, best recorded by horizontal-component instruments. Generally, *Sg* arrivals start with large amplitudes that successively decrease as the time increases, forming the coda of the event. Coda duration is related to the magnitude. *Rg* phases, best recorded on vertical-component seismograms, often display a clear

dispersion. As an example, a record from a regional earthquake is displayed in Figure 5. The first discernible phase is *Pn*, best recorded on the vertical component. It is followed by *Pg*, *Sn*, and *Sg*, which are recognizable on all three channels. Largest amplitudes are exhibited by the *Lg* wave trains on the two horizontal channels. The focal depth of about 15 km prevents the development of short-period *Rg* waves. Note the high-frequency character of all recorded phases.

Strong events (magnitudes about 6 and larger) recorded at local or regional distances ($\Delta < 10^\circ$) will produce seismograms with duration of tens of minutes, especially on long-period records. Associated large amplitudes of ground vibrations often saturate the analog recording system (clipped records) and the resulting seismogram is not of much use except for measuring the arrival time and polarity of the very first recorded phase. In this and many other respects, digital systems with higher dynamic range are superior to analog instruments.

Similar to the low-velocity-layer, LVL, in the upper mantle, there is also a low-velocity channel in the deep ocean. Depending upon the salinity and temperature of water, the sound velocity decreases from the sea surface to a minimum of about 1.5 km sec^{-1} at about 700–1300 m depth and increases again from that depth to the bottom. The depth region of low velocity in the ocean, called SOFAR (sound fixing and ranging), provides extremely favorable conditions for long-distance propagation of a special type of high-frequency seismic wave.

Island and coastal seismographic stations frequently record these waves termed *T* waves (tertiary waves) arriving after *P* and *S* and characterized by propagation within the oceans as ordinary sound waves. Seismic waves emitted by earthquakes near the sea bottom or by submarine volcanic eruptions are refracted through the sea floor and propagate as sound

FIGURE 4 Two records with remarkably well developed short-period *Rg* waves with normal dispersion within a period range from 3 to 1 sec. *Rg* dominates the records, emphasizing the shallow focus depth, of probably not more than 1–2 km. Top: rockburst of 19 January 1963, magnitude unknown, recorded at Uppsala, Sweden, $\Delta = 148 \text{ km}$; bottom: rockburst of 19 January 1963, recorded at Göteborg, $\Delta = 300 \text{ km}$. FIGURE 5 Vertical (*Z*) and horizontal (*N*, *E*) component seismograms from a moderate size regional earthquake. The event occurred off coast of southern Norway on 29 May 1999 (magnitude $M_L = 3.9$, $h = 10$ km). The traces are analog displays of broadband digital recording made at Uddeholm, Sweden, at an epicentral distance of 530 km.

(longitudinal) waves through the ocean. The propagation of *T* waves, generally through the SOFAR channel (Bullen and Bolt, 1985) or by multiple reflections between the sea floor and the sea surface (Båth and Shahidi, 1974), is very efficient and observations at distances as large as about 80° have been reported (Kulháněk, 1990). The first observation of *T* waves was made by D. Linehan in 1940.

T waves are best recorded by ocean-bottom seismometers (OBS) and by coastal and island stations (see Plate 21.2). However, instruments deployed further on land sometimes also record clear *T* waves after a water-land conversion of sound waves into *P*, *S* or surface waves propagating over the land portion of the total transmission path. If this is the case, the labeling is *TPg*, *TSg*, and *TRg*, reflecting the fact that the path of propagation over the land is within the crust. Examples of recorded *TSg* phases are given in Figure 6 and in Plate 4. *T* waves are short-period waves, with periods usually less than 1 sec, recorded exclusively by short-period seismographs. On records, they often exhibit rather monochromatic oscillations with a gradual increase and decrease of amplitudes of total duration up to several minutes. When compared, for example, with *P* waves, there is no sharp onset in the *T* wave group, which obviously creates difficulties when reading the *T* arrival times or when identifying phases within the *T* wave group. In general, there is great variety in the appearance of *T* phases due to the dependence upon the bottom topography in the vicinity of generation, oceanic stratification, and water-land conversion and transmission (Båth and Shahidi, 1974).

Observed *T* phases have proved very useful in discriminating between underground nuclear explosions, detonated beneath oceanic islands, and tectonic earthquakes (Adams, 1979). For this type of explosion, the energy is injected directly into the SOFAR channel and recorded *T* phase amplitudes often exceed those of associated *P* wave by a factor of up to 30 (see Plate 4).

As follows from the above description, for epicentral distances less than about 10° , the wave propagation is rather complicated. The seismogram appearance varies from place to place due to regional variations in the crust structure and, consequently, for this distance range it is difficult to list generally valid clues for record interpretation. Nevertheless, some of the following principles may guide the analyst to correctly read seismograms of local and regional earthquakes.

Predominant periods of recorded crust phases such as *Pg*, *P**, *Pn*, *Sg*, *S**, *Sn*, etc. are normally less than one second and hence are best recorded by short-period instruments. *Rg* periods are usually not longer than several seconds.

1. It has often been observed that *Sg* has the largest amplitude (for cases when large short-period *Rg* is missing), best seen on horizontal-component records.
2. For epicentral distances less than about 200 km (depending upon the crust structure and focal depth), the first-arriving phase is *Pg*. For larger distances, *Pn* arrives first.

FIGURE 6 Short-period vertical-component record from a shallow ($h = 33$ km) earthquake in Norwegian Sea made at Umeå, northern Sweden. This earthquake occurred on 21 November 1967 ($m = 5.4$) at a distance of 10° from Umeå. The seismogram shows clear P and S onsets, separated by 107 sec. Approximately 6 min after P , an onset labeled TSg is identified on the record. It corresponds to a wave propagating through the water as a sound wave and, subsequent to a water–land conversion and refraction, as Sg over the land path. In this particular case, the land path is about $1/3$ of the total travel length. The TSg wave shows oscillations with periods around 1 sec and gradually increasing and decreasing amplitudes. The whole TSg wave train lasts for about 2 min. (Reprinted from Kulhánek (1990) with permission from Elsevier Science.)

3. Near-surface events from distances less than about 600 km often generate short-period Rg with clear dispersion, best seen on vertical channels.
4. Local and regional earthquakes of low or moderate magnitude are characterized by short total record duration, usually not longer than several minutes.
5. Island and coastal seismographic stations frequently record various kinds of T phases.

It is not always possible for analysts to correctly identify crust phases from the records of a single station, although this may be easier if several stations of a network are read together. If there is doubt about correct interpretation, a phase should simply be identified as P or S .

2.2 Body Waves; Recording Distances $10\text{--}103^\circ$, Shallow Events

Seismologically speaking, the mantle differs from the overlying crust also in the fact that, in the first approximation, it may be considered as a laterally homogeneous, i.e., as a spherically symmetric body. Seismic wave velocities indeed increase with depth; however, the regional (lateral) irregularities typical for the crust are less distinct in the mantle. Some workers consider the distance range between 20° or 30° and 103° as ideal for recording not only the direct P and S waves but also the whole family of reflected and converted waves. Travel paths of these

waves are dominated by the mantle and corresponding seismograms are relatively simple.

To explain various features of waves traveling through the mantle, let us consider the Earth's cross section, a surface focus event, and travel paths of the more important body waves depicted in Figure 7.

At distances around 10° , Pn and Sn become difficult to identify in the records, except in some shield areas and other regions with relatively uniform structures. Instead, P and S phases become visible on seismograms. P is usually stronger on the vertical component, while S is more clearly seen on horizontal components. S often exhibits wave trains with longer periods when compared with corresponding P . Large-amplitude S waves are often observed at distances of up to about 100° .

Body waves that turn within the mantle and undergo no reflection between the focus and the recording station are labeled with a simple symbol P or S . Rays corresponding to travel paths of these direct waves (P or S), also called elementary waves or main waves, are displayed in Figure 7a. They depict paths of least travel time from the focus of the earthquake to the recording site. Waves reflected one or more times from the free surface give rise to singly or multiply reflected P or S . For example, the direct P reflected from the free surface back into the mantle once or twice, is called PP or PPP , respectively. In the same way, we have also SS , SSS , etc. Each letter, P or S , in the phase name defines one leg of the propagation path. Considering also the conversion from P to S ,

FIGURE 7 Examples of propagation paths of direct and reflected waves in the Earth's interior. Different shadings show the mantle, outer core, and inner core. (a) Examples of waves generated by the surface focus, F , of the earthquake, which radiates both P and S waves. Solid and dashed rays are used to distinguish between P and S waves, respectively. For notation see the text. (b) Examples of propagation paths of depth phases and their notation. Waves begin at the deep focus, F , of the earthquake. (c) Examples of propagation paths of direct P waves, P waves diffracted around the core–mantle boundary, and P waves reflected downward at a discontinuity at 650 km depth. The discontinuity and the shadow zone (103 – 144°) are shaded. (d) Propagation paths of P waves traveling through the Earth's core. The shadow zone is shaded and B denotes the caustic point. Rays are numbered in the order of increasing steepness of the initial descent. For details see the text. (Reprinted with modifications from Kulháněk (1990) with permission from Elsevier Science.)

and vice versa, on reflection, we may observe the wave denoted PS which travels as P from the focus to the reflection point at the free surface and from that point to the recording station as S . PS and SP appear only at distances larger than 40° . For a wave leaving the focus as P and twice reflected/converted from the free surface, we have four possible cases, namely PPP , PPS , PSP , and PSS . Some of these waves are sketched in Figure 7a. Obviously, we could continue with three and more reflections/conversions and form the corresponding wave symbols. However, from experience we know that it is quite seldom that three and more reflections from the Earth's free surface are clearly visible on actual seismograms. For distances larger than about 40° , the free-surface-reflected phases become very distinct. At distances around 100° and larger, PP and SS often belong to the largest recorded body waves.

The symbol c is used to indicate a single upward reflection, i.e., a reflection back into the mantle from the outer core–mantle boundary. For instance, ScP (Fig. 7a) corresponds to an S wave that travels down from the focus and is reflected and converted into the P type wave at the CMB and finally is recorded at the Earth's surface as ScP . A straightforward

extension provides PcP , ScS , and PcS . Because these phases emerge steeply, ScP is usually stronger on vertical components than PcS . Large reflected core phases are usually recorded at shorter epicentral distances, say at 40° or less. At distances around 39° , ScP and PcS (surface foci) are often contaminated with the arrival of direct S and the phase separation is difficult. When the ray path of PcP grazes the outer core boundary, the combination of direct P and PcP is called P diffracted. This case is discussed in more detail below. Core-reflected waves together with $PmKP$ (see Section 2.3 for notation), recorded from earthquakes at a wide range of distances and focal depths are used to study the properties of the core–mantle boundary.

Waves ascending from the focus to the free surface (in continents) or to the sea bottom (under oceans) and reflected back into the mantle, are commonly called depth phases and are denoted by a lower case prefix: p for longitudinal and s for transverse waves. We can easily list the four possibilities of reflections near the epicenter, which are pP , sP , pS , and sS (Fig. 7b). The first case, for example, denotes a wave that traveled upward from the focus as P (short leg) and was reflected back off the free surface again as P (long leg). Depth

phases, primarily pP , are the most important phases routinely used in focal-depth estimations. It is quite obvious that the deeper the focus, the later is the pP phase in relation to P . Hence, accurately measured arrival-time differences $pP-P$ are reliable indicators of the depth of the focus. In the case of a deeper focus, it is sometimes possible to recognize several different reflections from the free surface. Such waves are then labeled pPP , pPS , pSP , and pSS in the case of waves with their short leg as P . Logically, sPP , sPS , sSP , and sSS denote corresponding waves with short leg as S (Fig. 7b). Interpretation of depth phases must be done with utmost care since, for example, pP from a deep earthquake can easily be erroneously interpreted as P when the first arrival (P) is weak. Depending on focal orientation and other factors, sP may be stronger than pP and may be mistaken for it. Depth phases are sometimes stronger than the main P wave, and may be the first readable phase.

Events in the upper mantle sometimes generate visible but weak precursors to pP . These are Moho underside reflections labeled pMP . They are best observed on long-period records from deep-focus earthquakes; they show the same polarity as pP (Schenk *et al.*, 1989) but their correct identification is usually difficult. In a similar way, water-surface reflections are denoted pwP .

The lower-case symbol d (or its value in kilometers) inserted between PP , SS , etc. has been introduced by B.A. Bolt to indicate seismic waves reflected from “secondary” discontinuities in the upper mantle. For example, symbols $P400P$ or $P650P$ (Fig. 7c) specify P waves reflected at the underside of a discontinuity at a depth of 400 or 650 km, respectively. These phases arrive at the recording station ahead of the expected (calculated) arrival time for the main PP phase and are frequently interpreted as reflections from upper-mantle discontinuities (i.e., as PdP). However, when the arrival time cannot be explained in terms of known discontinuities as PdP , we call these onsets early PP or precursors to PP .

2.3 Body Waves; Recording Distances 103° and Larger, Shallow Events

It was noticed in the early days of observational seismology that amplitudes of direct P waves decay dramatically at distances larger than about 100°. The short-period P waves reappear consistently on records, first at distances of about 140° and larger. Correspondingly, the distance range $103^\circ < \Delta < 140^\circ$ is called the shadow zone. Within this zone, there is no penetration of direct high-frequency P waves due to the wave diffraction around the Earth’s core (Fig. 7c). The last direct P wave reaches the Earth’s surface at an epicentral distance of about 103° where the shadow zone produced by the Earth’s mantle commences. P waves traveling beyond this distance creep around (are diffracted by) the core–mantle boundary and lose a large part of their energy there, so that only weak, diffracted P phases are observed in this distance range. Similarly

to dispersion, diffraction also depends on the wave period (or frequency). The longer-period waves can diffract further into the shadow zone than shorter-period waves. The diffracted P waves are labeled $Pdif$ or $Pdiff$. Seismological centers like the National Earthquake Information Center (NEIC) in Golden, Colorado, or the International Seismological Centre, ISC, in England use $Pdif$. On seismograms, $Pdif$ waves usually show small amplitudes and emergent or gradual onsets, and the energy shifts to the long-period section of the spectrum. Long-period $Pdif$ are sometimes observed out to distances of 160° or more. S waves are affected at the core–mantle boundary in a similar way; the symbol $Sdif$ or $Sdiff$ is used for diffracted S waves. The shadow zone for S waves on the side of the Earth opposite the earthquake extends over all epicentral distances from about 103° to -103° (257°).

Direct P and S waves and corresponding reflections are easily distinguishable from surface waves. The former usually occupy the period interval from, say, 1 to 10 sec, while the latter show large amplitudes (surface or shallow shocks) and periods in the interval from about 10 to 100 sec. The period of S waves increases with distance and, in cases of multiple reflection, may even reach several tens of seconds.

As mentioned above, the limiting ray path, which is tangential to the core in the real Earth, is that corresponding to an epicentral distance of about 103°. P and S waves recorded at distances greater than 103° graze or strike the surface of the core, the wave pattern becomes rather complicated, and amplitudes decay dramatically. Seismic waves that leave the source with a steeper descent than the grazing waves may either reflect from the core–mantle boundary or refract into the core. The former are reflected back into the mantle as PcP , PcS , ScP , or ScS , while the latter, called core phases, are refracted downward and enter the core. The refraction is rather sharp because of the sudden significant drop of P velocity beneath the core–mantle boundary.

A P wave leg in the outer core is denoted by K (from German *Kernwellen* for core waves). It has to be emphasized that the symbol K always represents a P wave since S waves do not enter the fluid outer core. After traveling through the outer core and following another partitioning (reflection or refraction) at the outer core boundary, it emerges at the Earth’s surface. Thus, we can form the four symbols for waves that have traveled through the outer core: PKP , PKS , SKS , and SKP . For example, the symbol PKS corresponds to a wave that starts in the mantle as a P wave, is refracted into the outer core as a P wave, and is finally, after mode conversion, refracted back in the mantle as S . The phase SKP is stronger on vertical components than PKS . These phases have a caustic near 130° and at this distance are often the only phase recorded on short-period instruments. Some of the seismic rays traversing the core are illustrated in Figure 7d. The notation PKP is sometimes abbreviated as P' .

For ray paths that are only slightly steeper than the ray grazing the core surface, corresponding PKP waves emerge

at the Earth's surface at distances beyond 180° (see Fig. 7d). As the rays (surface-focus event) enter the mantle more steeply, the core refractions become smaller and the rays emerge at the Earth's surface at increasingly shorter epicentral distances, until about 144° . For even steeper take-off angles of the initial ray paths, we see an increase of the distance of emergence up to 165° or so. The phenomenon may be viewed in terms of two *PKP* travel-time branches denoted *PKP1* and *PKP2* for the first and the second arrivals, respectively. Close to 144° , the waves from the two branches coincide and the waves constructively interfere, which gives rise to an energy concentration near that distance. The point of largest energy concentration is called a caustic point or simply caustic. The shape of corresponding travel-time curves is called triplication, indicating that three distinct travel-time branches exist at certain epicentral distance. It has to be stressed that neither *PKP1* nor *PKP2* enter the inner core, i.e., both these wave types have their deepest point of penetration in the outer core.

As we further steepen the initial ray path, we reach the family of rays that enter the inner core (Fig. 7d). These rays progress in a normal way, i.e., the steeper the initial ray path, the greater the distance of emergence from about 110° until at last there is a ray that passes through the Earth's center and reaches the Earth's surface at the antipode of the focus. *P* waves that traverse the inner core are denoted by *I*, giving rise to phases *PKIKP*, *PKIKS*, *SKIKS*, and *SKIKP*, although these are often still simply referred to as *PKP*, *PKS*, etc. Phases with an *S* leg in the inner core would include the letter *J*, such as *PKJKP*, but these have never been unambiguously identified on seismograms. Both the symbols, *I* and *J*, have to be accompanied on both sides by *K*. Rays corresponding to seismic waves reflected at the outside and inside of the inner core are called *PKiKP* and *PKIIKP*, respectively.

If the studied event is weak, *Pdif* is not clearly observed in the entire distance interval $\Delta > 103^\circ$ and the first arrival seen on the record will be that of *PKP*. At epicentral distances 110 – 120° , *PKIKP* usually provides the first onset discernible on the seismogram.

Near the caustic, i.e., around 144° , the wave train of recorded core phases becomes particularly complicated. It is first at distances beyond the caustic point where observed onsets may be separated into individual *PKP* branches (see Plate 21.18). The energy distribution changes with the increasing distance. *PKP1* is the dominant branch just beyond the caustic, up to about 153° . In records of weaker events (144 – 153°), *PKP1* is often the first visible onset since *PKIKP*, theoretically preceding *PKP1*, is too weak to be observed. As the distance increases, *PKP1* becomes weaker and vanishes from records at distances of about 160° and larger. For distances beyond, about, 157° , *PKP2* usually dominates the seismogram. Some workers prefer the nomenclature adopted from travel-time charts with branches denoted *AB*, *BC*, and *DF* (Jeffreys and Bullen, 1967). Arrivals associated with these branches are then labeled *PKP_{AB}*, *PKP_{BC}*, and *PKP_{DF}* and

correspond to *PKP2*, *PKP1*, and *PKIKP* arrivals, respectively. The *CD* branch (*PKP_{CD}*) is related to *PKiKP* arrivals corresponding to seismic waves reflected at the outside of the inner core. Waves that are multiply reflected at the underside of the inner core boundary are called *PKmIKP* ($m = 1, 2, \dots$).

PKIKP in the distance range from about 125° to the caustic is often preceded by early arrivals or precursors that can arrive many seconds ahead of the main phase. These are usually explained by scattering phenomena just above the core–mantle boundary.

In a similar way as for the mantle, we may define new phase names for the family of waves propagating through the core. For example, *PKKP* is a *P* wave that has been reflected from the inside of the core–mantle boundary. *PKKP* is often very pronounced on records made at distances between 60° and 80° . The sharp onset may easily be misinterpreted as a first *P* arrival of another event. *P* waves trapped inside the Earth's liquid core and with multiple *K* legs are called *PmKP*, where $m - 1$ provides the number of reflections from the underside of the CMB. Cases like *P4KP* and *P7KP* have been observed (Bolt, 1982).

PKPPKP, or for short *P'P'*, are *PKP* waves once reflected from the free surface back to a station in the same hemisphere as the focus. Since *PKP* has the caustic at 144° , the best chance to observe *P'P'* is around distances of $2 \times 144^\circ = 288^\circ$, or 72° if we take the shortest distance from source to station. *P'P'* is often well recorded, arriving about 30 min after the *P* phase when most of the coda amplitudes of preceding phases have already become faint, and it may in some cases be wrongly interpreted as a new *P* or *PKP*. The value 72° is also equivalent to $3 \times 144^\circ = 432^\circ$ or $(360^\circ + 72^\circ)$ so the phase *P'P'P'* is also strong at this distance, and may be observed for strong earthquakes about another 20 min after *P'P'*.

In the late 1960s, first observations of forerunners to *P'P'* were made. These were interpreted as *P'dP'*. Analogous to *PdP*, *P'dP'* waves are reflected at some discontinuity in the upper mantle. For example, *P'650P'* travels from the hypocenter to the other side of the Earth, where it is reflected back to the station from a layer 650 km below the surface. *P'650P'* passes through the core twice and on the seismogram precedes *P'P'* by about 2 min.

Let us now shift our attention from *P* to *S* waves. Similarly to *PKP*, there are *SKS* waves, i.e., *S* waves traveling from the earthquake source down through the mantle, incident at the outer-core boundary they undergo a mode conversion and as *P* (the *K* leg) transverse the liquid outer core. Following an inverse mode conversion, they again enter the mantle as *S* and emerge at the Earth's surface as *SKS*. Analogous phases to *PmKP* are *SmKS*. First *SKS* waves are observed at distances between 60° and 70° and the range of observations extends out to distances of 180° or so. Depending upon details in the structural model, *SKS* exhibits large amplitudes at a distance near 80° so that the best region for study of *SKS* waves is that between 70° and 90° . However, the phase identification has to

be made with utmost care since *SKS* waves recorded in this distance region have similar travel times as direct *S* waves. For Δ greater than about 82° , *SKS* arrives ahead of *S*. For distances shorter than about 95° , *SKS* is usually smaller than *S*; however, at distances beyond 95° , *SKS* amplitudes are often quite large (see Plate 21.14). Mistaking *S* for *SKS* and vice versa will adversely affect the estimation of epicenter location. Since the epicentral distance estimate is frequently governed by the observed arrival-time difference *S*–*P*, wrong *S* identification on the record will provide a wrong epicentral distance, which in its turn will result in erroneous location. *S* and *SKS* are best recorded on long-period horizontal-component seismograms. However, occasionally these body waves are also observed on short-period records, although the onset of the later of the two phases is usually not obvious due to the contamination by coda of the earlier phase.

2.4 Body Waves from Intermediate- and Deep-Focus Earthquakes

Early in the last century several investigators (Pilgrim, 1913; Turner, 1922) found a number of events with focal depths greater than 100 km. Somewhat later, Japanese scientists (Wadati, 1927; Shida, 1937) presented evidence that Japanese earthquakes occur at practically all depths down to 500 km. They based their conclusions upon observed *S*–*P* arrival-time differences, intensity distributions, and different appearances of intermediate- or deep-focus earthquakes and of those that take place at shallow depth. Wadati noted very early that the seismograms of intermediate-focus and deep shocks display rather impulsive and large *S* phases, shorter predominant periods, and less well-developed codas.

Later studies confirmed conclusions from Wadati's pioneering work that intermediate- and deep-focus shocks produce

simpler seismograms (see, e.g., Plate 21.3) with exceptionally well-recorded impulsive body waves, while surface wave amplitudes are relatively small. Strong depth phases, such as *pP* and *sS*, are also frequently very distinct on records from deep events. However, the duplication of principal phases by surface reflections often complicates the seismogram interpretation. Another important characteristic that accentuates the difference between shallow and deep shocks is the pattern of aftershocks. While large, shallow earthquakes are usually followed by numerous aftershocks, deep events (which may be multiple shocks) rarely show well-developed aftershock series (see, e.g., Wiens *et al.*, 1994).

As an example, Figure 8 displays three-component records made at a teleseismic distance from the Hindu Kush earthquake, which occurred at a depth of 200 km. Note the rather impulsive appearance of *P*, *pP*, *PP*, *PcP*, and *S* and *ScS* (*E*–*W* component) which are all easily identified on the seismogram. Practically no surface waves were recorded from this event.

Strong intermediate-focus and deep earthquakes occur in several different seismically active regions. Among these are island arcs such as Tonga-Kermadec Islands, the Marianas, New Hebrides Islands or the Aegean arc; continental margins with deep ocean trenches like Central America and western South America; and mountain chains, e.g., Himalayas (Hindu Kush) or Carpathians. About one-fifth of all reported earthquakes take place at a focal depth exceeding 70 km. Among the deepest known earthquakes are three in the Flores Sea area, on 25 August 1933, 29 June 1934, and 30 June 1943. Their depths are given by Gutenberg and Richter (1938) as 720 km, although other agencies have placed them rather shallower. ISC records contain four recent events in the Fiji-Tonga area with depths greater than 750 km: 15 January 1981 (765 ± 17 km), 21 November 1982 (769 ± 31 km), 25 October 1972

FIGURE 8 Seismograms from an intermediate-focus earthquake in the Hindu Kush region on 4 September 1990, made at the Swedish station Uppsala at an epicentral distance of 41° . The traces exhibit three components of long-period records. Note the rather impulsive character of recorded phases. Virtually no surface waves have been recorded from this event.

(806 ± 84 km), and 7 May 1971 (848 ± 26 km). These events are all small and not widely recorded, and their depths, particularly those of the deepest two, cannot be regarded as well established. Occasionally, deep-focus earthquakes occur in rather unexpected geographical areas. For instance, up to 1954 it was generally accepted that the geographical extent of deep quakes is limited to the Circum-Pacific belt and the areas mentioned above. However, on 29 March 1954, an isolated major earthquake occurred in southern Spain at a depth of 630 km. A smaller earthquake occurred at the same location on 30 January 1973.

Even though several alternative hypotheses to explain deep earthquakes have been launched in the past (e.g., contraction of the Earth due to cooling), today nearly all seismologists agree that deep and intermediate-focus events are associated with the subducting lithosphere, which fits nicely with the idea of plate tectonics. It is of course, still possible that individual shocks may not be related to subduction. Notwithstanding the unifying frame of plate tectonics, it is likely that deep and shallow events are generated by fundamentally different modes of rock failures (see, e.g., Frohlich, 1989; Green, 1994; Kirby *et al.*, 1996).

On the whole, the most distinctive features of a large intermediate-focus or deep earthquakes recorded at teleseismic distances pertinent to seismogram interpretation are the seismogram's simplicity, small amplitudes of or even absence of surface waves, and an impulsive shape of body waves. With some elementary experience, all these characteristics may often be revealed as the eye scans the seismogram. In a more retrospective-type interpretation, the absence of aftershocks will support the classification of the shock as a deep or intermediate-focus event.

2.5 Surface Waves

With exception of very short epicentral distances, surface waves carry by far the largest amount of wave energy radiated by shallow and some intermediate-focus earthquakes. Contrary to other types of surface waves, propagation of *LR* waves is not limited to layered media; they can also be transmitted through a homogeneous half-space (semi-infinite medium). The particle motion of Rayleigh waves follows a retrograde elliptical orbit in the vertical plane containing the direction of propagation. At the Earth's surface, the amplitudes in the vertical and horizontal directions are related roughly as 3:2. Hence, Rayleigh waves are usually best seen on vertical-component seismograms. Amplitudes of *LR* waves decrease rapidly (exponentially) with increasing depth. For example, at a depth equal to one wavelength, the vertical and horizontal amplitudes fall to 0.19 and 0.11 of their free-surface values, respectively. The velocity of Rayleigh waves in a homogeneous medium, c_R , lies between 0.87 and 0.96 times the *S*-wave velocity, v_S , of the half-space. For many rock materials the Poisson ratio is approximately 0.25 which leads to a relation $c_R = 0.92 v_S$.

Consider now a thin superficial layer superimposed on a homogeneous half-space. Assuming that the *S*-wave velocity in the layer is lower than that in the material below, Love waves designated *LQ*, can be transmitted through the layer without any significant penetration of energy into the lower medium. Love waves may, therefore, also be considered as channel waves, in this particular case transverse waves, trapped in the superficial layer. In contrast to Rayleigh waves, Love waves show no vertical motion, since particles excited by propagating *LQ* waves are polarized in the horizontal plane and perpendicular to the direction of propagation. Consequently, traces of *LQ* waves should be looked for on the horizontal-component seismograms. Love waves propagate faster than Rayleigh waves with velocities limited by *S*-wave velocities in the layer and the half-space. The mean velocities of propagation are 4.43 and 3.97 km sec⁻¹ for *LQ* and *LR*, respectively (Bullen and Bolt, 1985).

The analyst has essentially two clues to distinguish *LQ* waves from *LR* waves. The first is the different particle motion. While Rayleigh waves usually show the largest amplitudes on vertical-component records, Love waves are best displayed on horizontal-component seismograms. The second clue is the different propagation velocities. Both *LQ* and *LR* propagate more slowly than *P* or *S*, but since *LQ* propagates faster than *LR*, they are recorded ahead of *LR* waves.

Surface waves traveling through layered media often show appreciable normal dispersion which, as time goes on, continually changes the shape of both *LQ* and *LR*. Due to the dispersion, the original appearance of the wave train becomes disturbed on the seismogram by long-period waves advancing toward the beginning of the wave train as it travels through the medium. Plots of wave velocity as a function of period (frequency) are called dispersion curves. The shape of the curves depends strongly upon the character of the propagation path. In the period range from about 2 to 60 sec, continental travel paths exhibit dispersion curves for *LR* waves with group velocity gradually increasing from 2 to almost 4 km sec⁻¹. For *LQ* waves, the group velocity starts at about 2.5 km sec⁻¹ and reaches values close to 4.5 km sec⁻¹ at periods of several hundreds of seconds. Dispersion curves associated with oceanic travel paths show a rather abrupt change in the short-period range. At periods around 15 sec, the velocity of *LR* increases sharply from about 1.5 to more than 3 km sec⁻¹. For *LQ* waves, a sudden velocity rise from about 3 to 4 km sec⁻¹ is seen at periods around 7 sec (Bullen and Bolt, 1985).

An experienced analyst will distinguish between recorded surface waves that have traveled along pure oceanic or continental paths. Dispersion characteristics of oceanic routes give rise to long wave trains with rather slow and sometimes hardly visible period change over relatively long (5–10 min) record segments. A typical seismogram is displayed in Plate 21.17. In contrast, continental paths generate a characteristic fast period decrease with time, which is often easily recognized by inspecting several minutes of the records (see, e.g.,

Fig. 1 and Plates 21.8 and 21.13). As indicated above, the exact shape of dispersion curves depends upon the structure traversed. This means that empirical dispersion curves for LQ or LR waves provide the researcher with remarkably effective probes for studying the structure of the traversed medium (so called inverse problem).

Dispersion curves show a rather complicated pattern with several local minima and maxima. Surface waves traveling with these minimal or maximal group velocities are called Airy phases. On seismograms, an Airy phase is characterized by a constant-frequency compact wave train, often with a remarkable amplitude build-up of dispersed surface waves traveling by fundamental-mode propagation (Fig. 9).

At short epicentral distances, it is difficult to identify LQ and LR waves because they are often contaminated by large-amplitude S waves (Plate 21.9). At large distances, the identification is rather simple since LQ and LR waves dominate the record (shallow events) and are significantly delayed with respect to S waves. On seismograms, surface waves may be spread over several hours.

Dispersion curves for LR waves (both the oceanic and continental paths) show a local minimum for periods around 200 sec. In the period range from approximately 50 to 200 sec, the group velocity is monotonically decreasing with increasing period. Physically this means that in this period range long-period Rayleigh waves follow the laws of inverse dispersion. Observations of this interesting phenomenon are rather scarce, but one example can be found in Plate 21.10.

Periods of the largest (maximum amplitude) recorded surface waves show a clear positive correlation with epicentral distance. For example, for distances 10° , 50° , and 100° , the expected minimum periods, $T_{\min}$, of the largest continental Rayleigh waves are of the order of 7, 13, and 16 sec, respectively (Willmore, 1979). For oceanic passages, the periods can

be somewhat longer. Also, the time occurrence of the beginning of the maximum movement, $T_{R\max}$ (Rayleigh wave), with respect to the first onset of P waves, T_P , is obviously distance-dependent. Table 1 gives the time differences $T_{R\max} - T_P$ for various epicentral distances Δ . Hence, the position of the maximum amplitude in the LR wave train, with respect to the P arrival, and its period offer the interpreter other important information on the approximate epicentral distance of the earthquake.

As mentioned earlier, surface-wave amplitudes are large only close to the Earth's free surface and decrease rather rapidly with increasing depth. Consequently, a shallow-focus earthquake will usually generate large, dominating surface waves, while deep-focus event of the same magnitude will generate abnormally small surface waves. This feature obviously provides the interpreter with a valuable tool for discriminating, at first glance, between shallow events and deep-focus earthquakes. An exception to this rule is provided by seismograms of underground explosions. These events are obviously shallow shocks with focal depths not exceeding several kilometers. Nevertheless, they generate only very weak surface waves even for explosions of body-wave magnitudes around 7 (Plate 21.11).

Comparatively long-period surface waves, so-called mantle waves, have been observed from large distant shocks. These waves can be either Love or Rayleigh wave type with periods from somewhat less than one minute to several minutes. The speed of the LQ type mantle waves is often nearly constant at 4.4 km sec^{-1} and the wave has an impulsive shape on the seismogram. The LR type mantle waves travel with a velocity between 3.6 and 4.1 km sec^{-1} . Since the wavelength of mantle waves varies from several hundreds to more than a thousand kilometers, these waves are affected by a large part of the Earth's mantle (Plates 21.10 and 21.12). An interesting feature

FIGURE 9 Medium-period, vertical-component seismogram from the earthquake of 21 October 1964 ($m = 5.9$, $h = 37 \text{ km}$) in India–China border region, made at Uppsala, Sweden, at an epicentral distance of 59° . The trace illustrates a record with a distinct Airy phase of the fundamental-mode Rayleigh waves characterized by a practically constant-frequency wave train. Observe the remarkable amplitude build-up and fall-off within three swings. The trace also exhibits the direct P and an unidentified phase arriving about 17 sec after P . The second phase, when interpreted as pP , provides a focal depth of 70 km. (Reprinted with modifications from Kulhánek (1990) with permission from Elsevier Science.)

of mantle waves is their repeated appearance on records, as they can travel multiple orbits around the Earth. The LQ type mantle wave was given the label G (after B. Gutenberg) and the LR type mantle wave was labeled R . The older nomenclature sometimes uses W instead of R (from German *Wiederkehrwellen*, meaning repeated waves). G waves that propagate along the minor and major arc of the great circle path are labeled $G1$ and $G2$, respectively. Waves that have traveled additional orbits around the Earth are denoted $G3$ and $G4$, and so on. Accordingly, we have $R1$, $R2$, $R3$, $R4$, etc. (cf. Chapter 11 by Romanowicz). On many occasions, observations of up to $G8$ and $R8$ have been made. As an exceptional case we may mention records of the 1960 Chile earthquake, $M = 8.3$ (surface-wave magnitude). Seismograms made at Uppsala, Sweden, reveal mantle waves $G20$ and $R20$ that have traveled a total distance equal to that from the Earth to the Moon (Båth, 1979).

2.6 Volcanic Earthquakes and Unusual Seismic Sources

Volcanic earthquakes, discovered by L. Palmieri at the Vesuvius Observatory in 1855, are caused by sudden opening

of channels in crustal rocks, rapid changes of motion of magma, excessive accumulation of gas pressure in the crust, roof collapses of subterranean channels emptied of magma, and so on. According to Minakami (1959a,b, 1960) or Tazieff and Sabroux (1983), volcanic earthquakes are classified into three groups: A-type earthquakes with foci between 1 and 10 km deep; B-type earthquakes with foci at depths of 1 km or less; and explosion-type earthquakes taking place at the very surface of the Earth. Another categorization of volcanic earthquakes can be found, for example, in Tokarev (1983). Close to active volcanoes, we also frequently detect so-called volcanic tremor, which is due to long-duration, more or less continuous, volcanic vibration. Whereas volcanic earthquakes are clearly isolated events separated in time from each other, volcanic tremor shows rather spasmodic or harmonic behavior. It is associated with flow of underground magma, oscillations in magma reservoirs, explosions of volcanic gases, and the like. Examples of seismograms from volcanic earthquakes are given in Plate 21.5.

Among other sources of earthquakes one can mention implosion or collapse earthquakes, impact earthquakes due to collisions of meteorites with the Earth's surface (e.g., the Tunguska, Siberia, impact in 1908), low-magnitude icequakes generated by temperature changes in glaciers, earthquakes related to large-scale landslides, etc. These are some of the types of earthquakes that, together with tectonic earthquakes, volcanic earthquakes, and oceanic microseisms belong to the category of natural seismic sources. There is also a variety of man-made seismic sources such as industrial or military explosions and various types of cultural noise (traffic, industry, construction works, sonic booms), which are examples of controlled sources. Other types of man-made seismic sources are induced or triggered events (high dams, mining activity, fluid injections). Examples of records from some unusual seismic sources are exhibited in Plates 21.6 and 21.7.

For earthquakes other than tectonic or volcanic, the source identification is usually a task in itself. A classical example of source identification is the well-known problem of discriminating underground nuclear explosions from earthquakes. Even on a regional scale, reliable identification of conventional explosions is of importance for the correct estimation of seismic properties of an area. The same applies also to other man-made seismic sources. More detailed discussion goes beyond the scope of the chapter and the interested reader is referred to other works for more information.

3. Seismogram Examples with Interpretations

This section comprises a collection of 18 Plates with actual seismograms (see attached Handbook CD). Included are also phase interpretations and short commentaries of specific features reflected in the displayed records. Collected seismograms

were made at a number of seismographic stations by a variety of instruments covering different frequency bands.

Exhibited records cover the whole range of epicentral distances, a large range of focal depths and various types of propagation paths. Different seismic sources are presented. More classical records as well as analog displays of digital

records are shown. The arrangement of Plates is according to epicentral distance except for records from volcanic earthquakes and exotic sources, which follow the suite of local and regional events. For the ease of the reader, common notations of seismic waves used throughout the text and in the following Plates are listed in Table 2 in the order in

TABLE 2 Nomenclature of Seismic Phases

Symbol	Meaning
Local and regional events	
$\bar{P}, S$	Direct compressional or shear wave traveling through the upper crust (observed only at very short epicentral distances)
P_g, S_g	Compressional or shear wave in the granitic layer of the crust
PmP, SmS	Compressional or shear wave reflected at Moho
Pn, Sn	Compressional or shear wave traveling along (just beneath) the Moho discontinuity, so called head wave
P^*, S^* (or Pb, Sb)	Compressional or shear wave traveling along (just beneath) the Conrad discontinuity
pPn	Depth phase that leaves the focus upward as P , is reflected as P at the free surface and continues further as Pn
sPn	Depth phase that leaves the focus upward as S , is reflected and converted into P at the free surface and continues further as Pn
Rg	Short-period crustal surface wave of Rayleigh type
Lg	Guided crustal wave traversing large distances along continental paths
T	Compressional wave propagating through the ocean (tertiary wave). T phases are occasionally observed even at large teleseismic distances
TPg (TSg, TRg)	Wave that travels the ocean and land portion of the total transmission path as T and Pg (Sg, Rg), respectively
Teleseismic events	
P, S	Direct compressional or shear wave, so called elementary or main wave
PP, PPP, SS, SSS	P or S wave reflected once or twice at the Earth's surface
SP	S wave converted into P upon reflection at the Earth's surface
PPS, PSP, PSS	P wave twice reflected/converted at the Earth's surface
PcP, ScS	P or S wave reflected at the core–mantle boundary
PcS, ScP	P or S wave converted respectively into S or P upon reflection at the core–mantle boundary
pP, pS, pPP, pPS , etc.	Depth phase that leaves the focus upward as P (p leg), is reflected/converted at the free surface and continues further as P, S, PP, PS , etc.
sP, sS, sPP, sPS , etc.	Depth phase that leaves the focus upward as S (s leg), is reflected/converted at the free surface and continues further as P, S, PP, PS , etc.
pMP	P wave reflected at the underside of Moho
pwP	P wave reflected at the water surface
PdP	P wave reflected at the underside of a discontinuity at depth d in the upper part of the Earth. d is given in kilometers, e.g., $P400P$.
Pc, Sc or $Pdif, Sdif$	P or S wave that is diffracted around the core–mantle boundary
PKP (or P')	P wave traversing the outer core
PKS	P wave converted into S on refraction when leaving the core
SKS	S wave traversing the outer core as P and converted back into S when again entering the mantle
SKP	S wave converted into P on refraction into the outer core
$PKP1, PKP2$ or PKP_{BC}, PKP_{AB}	Different branches of PKP
$PKIKP$ or P'', PKP_{DF}	P wave traversing the outer and inner core
$PKiKP$	P wave reflected at the boundary of the inner core
$PKIIKP$	P wave reflected from the inside of the inner-core boundary
$PKKP$	P wave reflected from the inside of the core–mantle boundary
$PmKP$ ($m = 3, 4, \dots$)	S wave reflected $m - 1$ times from the inside of the core–mantle boundary
$SmKS$ ($m = 3, 4, \dots$)	S wave converted into P on refraction at the outer core, reflected $m - 1$ times from the inside of the core–mantle boundary and finally converted back into S when again entering the mantle
$PKPPKP$ (or $P'P'$)	PKP wave reflected from the free surface, passing twice through the core
$P'dP'$	PKP reflected at the underside of the discontinuity at depth d in the upper part of the Earth. d is given in kilometers
LR	Surface wave of Rayleigh type
LQ	Surface wave of Love type
G	Mantle wave of Love type
R	Mantle wave of Rayleigh type
$G1, G2$	LQ -type mantle wave that travels the direct and anticenter routes. Waves that have, in addition, traveled once or several times around the Earth are denoted $G3, G4, G5, G6$, etc.
$R1, R2$	LR -type mantle wave that travels the direct and anticenter routes. Waves that have, in addition, traveled once or several times around the Earth are denoted $R3, R4, R5, R6$, etc.

which they are cited in the text. If not mentioned otherwise, the interval between time marks on displayed seismograms is 1 min.

Acknowledgments

This chapter was written at the Department of Earth Sciences, Seismology Programme, Uppsala University, Uppsala, Sweden. My thanks are due to my colleague A.J. Anderson who carefully read and commented on various parts of the manuscript. Invaluable indeed are the seismogram examples with commentaries that I have received from V. Barbosa (Plate 21.5), G. Choy (Plates 21.14, 21.15, 21.18), A. Plesinger (Plate 21.12), M. E. Reyners (Plates 21.3, 21.4), D. Seidl (Plate 21.17), R.A. Uhrhammer (Plates 21.6, 21.7, 21.10, 21.16) and M. Yamamoto (Plates 21.1, 21.2). I also wish to thank J. Ritsema and two anonymous reviewers for their constructive comments and suggestions, which improved the text.

Analysis of Digital Earthquake Signals

Frank Scherbaum

University of Potsdam, Potsdam, Germany

1. Introduction

The great progress made in the past several decades in seismology has been stimulated mainly by the availability of increasingly plentiful and improved seismic data. Our ability to collect, process, and analyze earthquake data has been aided by rapid advances in electronics and digital computers. Seismograms were mostly recorded using analog techniques up to a few decades ago. Except for very elementary tasks, such records are now considered of rather limited use because of low dynamic range, poor timing accuracy of the recording systems, and the lack of any convenient post-processing.

Modern digital seismograph systems consist of a cascade of analog and digital stages. The analog part of the system involves the seismometer, possible (pre-)amplifiers, and the analog antialias filter. Ideally these components act as high-pass, allpass, and low-pass filters, respectively. The antialias filter is required to assure that sampling is done in accordance with the sampling theorem (Stearns, 1975). The analog to digital (A/D) conversion is nowadays commonly based on the use of oversampling and decimation techniques. The output of the seismometer channels is first sampled at very high sampling frequencies (kHz range) and subsequently decimated (with proper digital antialias filtering) to the desired sampling rate. The reason for this is that the influence of the quantization noise—which directly limits the resolution of the sampling process—becomes less with higher sampling rates. The performance of the A/D conversion is additionally increased if only amplitude differences between a predicted sample value and the actual sample are digitized (differential sampling). For sampling frequencies much higher than the signal frequencies, these differences can become very small, especially if the trace is integrated before sampling. Therefore, low-resolution (down to one-bit) quantizers suffice. This is exploited in sigma-delta modulation, which is commonly used in high-resolution analog-to-digital converters (ADCs) for modern

digital recording systems (Proakis and Manolakis, 1992); see Figure 1.

Digital seismograms are merely sequences of numbers that must be processed in the context of analysis. This involves basic processes such as trace editing (spike removal, baseline correction, resampling), integration, differentiation, Hilbert transformation of traces, rotation of components, but also more advanced tasks such as frequency filtering of traces, detection and identification of different wavegroups, determination of exact onset times and true ground motion amplitudes, spectral analysis, polarization analysis, etc. Numerous software tools have become available for these purposes (Scherbaum and Johnson, 1993; Stammer, 1993; Chapter 85 edited by Snoke and Garcia-Fernandez; Chapter 85.5 by Goldstein *et al.*, 2001). In order to apply them correctly in observatory practice, a basic understanding of the fundamentals of system and filter theory is necessary. In other words, digital signal processing and system theory has become an integral part of digital seismometry and seismology. See Appendix 1 for a brief introduction into filter theory and Appendix 2 for a short discussion of the basic elements and characteristics of a digital seismograph system. These appendixes are given on the attached CD Handbook, under the directory \22Scherbaum.

2. Filtering of Digital Seismograms

Extracting relevant information from digital seismograms often requires intensive filtering of the recorded signals. This is especially true for broadband signals. One of the most common tasks is the removal of unwanted noise. This is usually done by restricting the frequency band to that of interest by low-pass and/or high-pass filtering, or by suppressing narrowband noise signals by band-rejection filtering. Numerous well-tested algorithms are widely available for the design of such

FIGURE 1 Building blocks of modern recording systems based on oversampling and decimation (sigma-delta modulation).

filters (Stearns, 1975; IEEE Committee, 1979; McClellan *et al.*, 1979; Parks and Burrus, 1987; Press *et al.*, 1992; Hamming, 1997).

For the purpose of consistent parameter estimation it is often desirable to convert recorded broadband seismograms into ones from a different seismograph system (simulation filtering). This allows the analyst to determine signal parameters in a manner consistent with other observatories. The simulated systems will most commonly belong to the standard-class instruments described by Willmore (1979). Since there is no single, optimum class of instruments, different instrument types must be considered for different tasks. For example, high-frequency teleseismic body waves are best analyzed on recordings of SP-instruments (class A),

long-period body waves and teleseismic surface waves are best analyzed on recordings of LP-instruments (class B), and regional body and surface waves are best analyzed on recordings of intermediate-band (class C) instruments. In addition, the Wood-Anderson instrument is of special historical importance for the determination of local magnitude. The magnification curves of some historical long-period and intermediate-band instruments are shown in Figure 2.

While the design of low-pass or high-pass filters is rather straightforward, the implementation of instrument simulation filters under general conditions is a complex task. To simulate the record of a certain seismograph system, the response of the original recording system, t_1 , has to be removed from the

FIGURE 2 Magnification curves of some long period and intermediate band analog seismographs. (From Kanamori, 1988, figure 8.)

record. The resulting signal has to be filtered with the response of the desired instrument:

$$\hat{Y}(z) = \frac{\tilde{T}(z)}{T(z)} \cdot Y(z) = \tilde{T}(z) \cdot Y(z) \quad (1)$$

$Y(z)$ and $\hat{Y}(z)$ are the z -transforms of the recorded and the simulated seismograms, respectively. The simulation filter can be thought of as a combination of an inverse filter for the actual recording system—this corresponds to the restitution of the input ground motion signal—and a synthesizing filter for the simulated recording system (Fig. 3).

There is no single best procedure for simulation filtering that performs well under all conceivable conditions (see also “Proceedings of the Seminar on Deconvolution of Seismograms and High-Fidelity Seismometry,” *J. Geophys.* **39**, 501–626, 1973). To date, the most advanced software package for automatically performing instrument simulation and deconvolution is the program PREPROC written by Miroslav Zmeškal (Zmeškal, 1996; Zmeškal and Plešinger, 1996).

It requires the calibration information be given in GSE format (GSE Waveform Data Format, 1990, 1995) and provides several methods for implementing the filter process. The theoretical background of the techniques used in PREPROC is discussed in Plešinger *et al.* (1996) and a discussion of the stability problems related to simulation filtering in general can be found in Scherbaum (1996).

3. Interpretation of Wave Onsets

Observational seismology is based to a very large degree on the analysis of seismic waveforms, especially on the recognition and interpretation of seismic wave onsets. Onset properties are used in numerous contexts ranging from earthquake location and the determination of focal mechanisms to source modeling and travel-time tomography. Quite recently, the properties of seismic onsets have received additional attention based on the fact that they may allow the distinction of different friction laws discussed in the context of modeling earthquake sources (Iio, 1992, 1995; Ellsworth and Beroza, 1995).

3.1 Onset Properties

An onset can be described by the shape of the discontinuity at the front of a signal. There have been only few quantitative treatments of onset properties (Seidl and Stammer, 1984; Seidl and Hellweg, 1988; Scherbaum, 1996; see Fig. 4). Seidl and Stammer (1984) have used the following definition:

The discontinuity of the signal front at $t=0$ is called an onset of order p , if $f^{(p)}(0+)$ is the last nonzero derivative (Seidl and Stammer, 1984).

A causal signal is a signal that is zero for negative times and starts to become nonzero at $t=0$. In this definition, the onset is defined by two quantities: The onset time at which the signal becomes different from 0 and the onset order, the “rate” at which it starts to increase with time for $t > \text{onset time}$ (Fig. 4a). Onset properties are affected in various ways by filters within the recording systems.

3.2 Change of Onset Properties by Causal Filters

One effect is a change in onset order caused by causal low-pass filters. This is best understood from the initial value theorem of the unilateral Laplace transform (Fig. 4b). This theorem states that the shape of the onset is controlled by the values of the Laplace transform times s for s going to infinity. If we consider only the imaginary axis of the s plane, that is, for $s \rightarrow j\omega$, or as it is written in Fig. 4b, $j2\pi f$, we can directly compare time-domain and frequency-domain behavior. In terms of time-domain and frequency-domain behavior, the initial value theorem tells us that if we change the shape of the high-frequency limit of the

FIGURE 3 Digital simulation of different seismographs systems. The simulation filter can be thought of as a combination of an inverse filter for the actual recording system and a synthesizing filter for the simulated recording system. Displayed are schematic sketches of the amplitude–frequency response functions of the contributing subsystems. (After Scherbaum, 1996.)

spectrum, we automatically change the onset order of a causal signal. Therefore, any causal low-pass filter will increase the onset order, i.e., smoothen the onset. If noise is present, the signal onset may no longer be detectable and the onset seems to be delayed. In other words, changes in the onset order may cause apparent time delays.

In addition to those apparent time delays, however, filters in general will also create real delays to signals. Let us assume a general filter—which could be a seismograph system—with the frequency response function $T(j\omega) = |T(j\omega)| \cdot e^{j\Phi(\omega)}$. For a purely harmonic input signal, $A_i \sin(\omega t)$, the output signal would become $A_i |T(j\omega)| \sin(\omega t + \Phi(\omega))$. Hence, it changes both the amplitude and the phase but not the frequency. The phase $\Phi(\omega)$ gives the amount by which the phase of a harmonic signal with frequency ω is advanced (in radians). This leads directly to the definition of the delay time for a harmonic signal, which is called the phase delay $t_{ph}(\omega)$ of a filter.

A harmonic signal with frequency ω , which is filtered with a frequency response $|T(j\omega)| \cdot e^{j\Phi(\omega)}$ is delayed by $t_{ph}(\omega) = -\Phi(\omega)/\omega$ seconds. For signals other than purely harmonic, the situation is more complicated. In the case of narrowband signals, the delay of the signal envelope (or center of gravity) is described by the group delay function $t_{gr}(\omega)$. For broadband signals, group delay and phase delay have no practical meaning. In this case the parameter of interest is the delay of the onset, the signal front delay t_{fr} . In the case of analog seismograph systems, which can be described by rational

transfer functions, the phase response function $\Phi(\omega)$ becomes constant for $\omega \rightarrow \infty$. This yields the important results that in this case the signal front delay becomes 0. At first glance this result suggests that in the context of onset time determination we only have to worry about apparent onset time delays caused by changes in the onset order of a seismic wavelet. However, in the context of simulation filtering of digital seismic data this is not true. In that case, the signal front delay depends on the sampling frequency. A more detailed discussion of group phase- and onset time delay can be found in Papoulis (1962).

3.3 Change of Onset Properties by Acausal FIR Filters

The change of onset properties by causal filters is only one part of the story in the context of modern data acquisition systems. Since the good performance of modern data loggers is commonly achieved by oversampling and decimation, these types of data loggers usually contain a cascade of symmetric decimation filters with a linear phase response. Such filters produce a constant time shift, which can be accounted for by changing the time stamp of the output stream. If the time shift is zero or is corrected for, the filter is called a *zero phase* filter. In this case the filter impulse response will begin at negative times and for very impulsive signals will produce acausal precursory oscillations.

FIGURE 4 Definition of onset order (a), and the onset distortions by causal low-pass filters (b).

As an example, Figure 5 shows in the top panel the overall effective impulse response of the 20 Hz data stream of the German Regional Seismic Network (GRSN). In terms of acausal filter artifacts, this is a worst-case scenario since it describes the distortion of an impulse, the sharpest seismic onset possible. In the lower panel one sees the response of the equivalent minimum phase filter, that is the filter with the same amplitude response but a minimum phase spectrum. In both cases, the input time for the impulse corresponds to time zero.

It can clearly be seen that the zero phase response (in the upper panel) starts out at negative times, which means it is acausal. Here, neither onset time nor onset polarity can be unambiguously determined. The exact onset time corresponds here to the time of the maximum of the impulse response. The onset time in the conventional sense—when the amplitude level exceeds some threshold—will always be determined too early, somewhere between $-t_1$ and $-t_2$. The maximum duration of visible artifact influence t_1 equals roughly half the duration of the impulse response of the last filter stage before decimation. The minimum duration of precursory artifact influence t_2 equals the time from the maximum to the first zero crossing of the overall filter response. In other words, onset

FIGURE 5 Overall impulse response of the 20 Hz data stream of the German Regional Seismic Network (upper panel). The lower panel shows the corresponding minimum phase response.

FIGURE 6 Potential onset time biases for different sampling frequencies on a Quanterra data logger. For the definition of t_1 and t_2 , see Figure 5. The effects are approximately the same for other data loggers.

times determined on the zero phase filtered trace will be always too early by at least t_2 , potentially up to t_1 .

In contrast, on the causal filter response, the onset time can be determined exactly, at least if no noise is present. In a noisy situation, the onset is probably determined slightly too late on a causal instrument because of the apparent onset time delay discussed above. This results in systematic differences between onset times determined from classical and modern data loggers (Scherbaum, 1997).

The magnitude of this effect depends strongly on the sampling frequency (Fig. 6). For the Quanterra data logger used in the German Regional Seismic Network, t_1 and t_2 as defined

above have been determined empirically for sampling frequencies from 0.01 to 80 Hz. Both scale roughly with the inverse of sampling frequency F_{dig} . This figure allows one to roughly estimate the potential effect of zero phase FIR filters on onset time determinations, but also to judge to what degree a precursory signal might be filter-generated. For example, for a 20 Hz data stream on a GRSN station, FIR filter artifacts are expected to show up for times between 0.08 and 0.7 sec. For the 10-sec data stream, the acausal influence of the filter reaches up to 200 (!) seconds. This plot is intended to illustrate that these times are nonnegligible.

Fortunately, for all purposes involving onset analysis, the FIR filter-generated precursory signals can be removed from the seismograms by post-filtration with specially designed all-pass filters (Scherbaum, 1996; Scherbaum and Bouin, 1997). The discussion of the techniques is beyond the scope of this article, however. More information and correction software is to be found on the accompanying Handbook CD as well as under http://butler.geo.uni-potsdam.de/FIR/fir_daaf.htm.

In conclusion, we have to worry about three different types of effects of seismic recording systems on onset times (Fig. 7):

1. Apparent time delays that are caused by changes in the onset order, for example by LP filtering. Any filter that changes the high frequency decay of a causal signal changes the onset order at the same time! In this case the amount of noise present in the data determines the apparent time delay.
2. Real-time delays, which are described for purely harmonic signals by the phase delay, for narrowband signals by the group delay, and for broadband signals by the signal front delay. While the signal front delay is zero for analog seismographs, it might be nonzero for digitally simulated seismographs.

Delays		Advances
Apparent delay	Physical delays	Onset advance by acausal FIR filters
Change of onset order by causal LP filters	Phase delay (harmonic signal)	Depending on recording system and sampling frequency
Depending on SNR	$t_{\text{ph}}(\omega) = -\Phi(\omega)/\omega$ (s)	
	Group delay (narrowband signal)	Distorts onset polarity also!
	$t_{\text{gr}}(\omega) = -\frac{d}{d\omega}\Phi(\omega)$ (s)	
	Signal front delay (BB signals)	
	$t_{\text{fr}} = \lim_{\omega \rightarrow \infty} t_{\text{ph}}(\omega)$ (s)	

FIGURE 7 Onset distortions caused by causal and acausal filters.

3. Time advances produced by zero phase FIR filters. The magnitude of this effect depends strongly on the sampling frequency. It should be noted that zero-phase FIR filters also influence the onset polarity determinations.

In addition to onset times, there are other time measurements on seismograms that play an important role in earthquake seismology. The determination of source size as well as of stress release is commonly based on the measurement of characteristic seismogram times, in the form of pulse duration, rise time, or in the spectral domain as spectral corner frequencies. The pulse rise time is commonly defined as the interval between the intersection of the tangent of the steepest rise of a wavelet with the zero-level and peak pulse amplitude (e.g., Gladwin and Stacey, 1974), $t_r = a_{\text{max}}/(\text{slope})_{\text{max}}$.

For an ideal zero phase low-pass filter that completely suppresses all frequencies above a corner frequency f_c , the minimum rise that can be determined becomes $1/(2f_c)$ (Scherbaum, 1996). Although this is strictly valid only for zero phase low-pass filters, it provides an easy way to get a rough estimate of the minimum rise time observable from a given recording system.

Seismometer Arrays—Their Use in Earthquake and Test Ban Seismology

A. Douglas

AWE Blacknest, Brimpton, Berks, UK

1. Introduction

The only way nuclear tests fired underground can be detected at long range is from the seismic signals that such tests generate. It is for this reason that the International Monitoring System (IMS) set up to provide data to enable the Comprehensive Test Ban to be verified has to include a network of seismological stations. Even when the signals are detected, however, it is not possible to recognize underground explosions unambiguously. The purpose of the Monitoring System is to provide data to allow those disturbances that are clearly natural to be identified, and those that have a high probability of being underground tests to be recognized. Should a suspicious disturbance be detected, it is up to the signatories to the Test Ban Treaty to ask the country suspected of carrying out the test to allow an international team to inspect the region around its estimated epicenter (that is, to carry out an On-Site-Inspection) to try to establish whether or not a nuclear test had taken place.

It was recognized when the first talks on banning nuclear tests began in 1958 that there is a need for ways of enhancing seismic signals in noise if a test ban is to be verified down to around a few kilotons (kt). One way proposed for suppressing

noise is by the use of arrays of seismometers, and this led to the establishment of the first such arrays in 1960. Since then more than 20 arrays have been put in (and most of these are still in operation), many principally to investigate the contribution that arrays can make to verification whereas others were installed by some nuclear weapon states specifically to detect the signals from foreign tests and so follow at least in part the nuclear weapons test programs of potential adversaries. Experiments have been carried out with a wide variety of array designs. Some of the most significant arrays to operate in the period since 1960 are listed in Table 1 and the designs of some of these are shown in Figure 1.

It is expected that the Monitoring System will allow the detection at long range of underground explosions with yields of 1 kt or more fired anywhere, and those with yields significantly less than this in most continental areas. As well as detecting the signals, the signal-to-noise ratio and bandwidth must be such as to aid discrimination between natural and suspicious seismic sources. The amplitudes of the short-period (SP) *P* waves (the most widely recorded seismic waves from underground tests) from explosions of 1 kt, are around a nanometer at 1 Hz at long range, which is below the seismic

TABLE 1 Examples of Short-Period Seismometer Arrays

Location	Code	Aperture (km)	No. of Seismometers	Operating Period	Remarks
Southeastern Norway	NORESS	3	25	Fall 1984 to date	Small aperture
Wichita Mts., OK, USA	WMSO	5	13	1964–July 1969	Small aperture
Eskdalemuir, Scotland	EKA	10	20	May 1962 to date	Medium aperture
Yellowknife, Canada	YKA	25	19	Nov 1962–May 1963 and Dec 1963 to date	Medium aperture. Gauribidanur (GBA) India and Warramunga (WRA) Australia are arrays of similar design
Billings, MT, USA	LASA	200	525	1965–1978	The large aperture seismometer array; 21 subarrays each of 25 seismometers

FIGURE 1 Examples of the layout used in short-period seismometer arrays. (a) Seismometer positions in some small- and medium-aperture arrays and a LASA subarray. The NORESS array is shown at twice the scale of the other arrays. (b) The subarrays within the LASA. The layout of YKA is superimposed on the figure to show the relative size of this array and the LASA.

noise level in the SP band over much of the Earth. Thus, it is only by using arrays of seismometers to suppress the noise that the monitoring system can be effective at the 1 kt level.

As well as allowing signals to be enhanced above noise, arrays can be used to determine the apparent velocity (speed and azimuth) of arrivals and hence their slowness, that is effectively the ray parameter, $dT/d\Delta$, where T is travel time and Δ is epicentral distance. If the arrival is a phase for which the slowness is known as a function of distance, the epicentral distance can be estimated and combined with the azimuth estimate to give a rough epicenter (and origin time) if the focal depth is assumed known. Conversely, slowness measurements can be used to test whether an initial identification is correct or can help with the identification of weak or unexpected phases (see, for example, Engdahl *et al.*, 1970; Cleary and Haddon, 1972; Cleary *et al.*, 1975; Barley, 1977). Arrays have also been used to measure $dT/d\Delta$ as a function of Δ for direct P (see, for example, Chinnery and Toksöz, 1967; Corbishley, 1970) and for P travel-time triplications (see, for example, Ram and Mereu, 1977; Simpson and Cleary, 1977).

Because of the large volumes of data generated by arrays, they were among the first seismometer stations to use digital computers to control the operation of the recording systems, and this naturally led to the automatic processing of recordings. The result has been an enormous growth in processing methods, with most of them aimed at detecting signals down to as low a magnitude as possible and providing rough estimates of epicenter and origin time of the signal source (see, for example, Ringdal and Husebye, 1982; Ringdal, 1990). Such automatic processing is necessary for test ban verification

where assessments may have to be carried out on most if not all the seismic disturbances detected. This could require investigation of upward of 20 000 disturbances each year.

Although arrays have several uses, in this review I concentrate on the unique feature of recordings from such stations, which is that they allow weak signals to be enhanced above noise. I then go on to show how this aids in the interpretation of seismograms and studies of source mechanisms particularly for test ban seismology—sometimes referred to as forensic seismology—in distinguishing between earthquakes and explosions. I therefore take as the definition of an array a spatially distributed set of seismometers all transmitting their outputs to a central laboratory to be recorded against a common time-base; the principal use of the outputs being to allow signals to be enhanced and noise to be suppressed. Recordings from networks of stations are sometimes combined to simulate an array, but it is only where a group of seismometers has been installed to operate as a unit that such a network can correctly be described as an array.

Although much research has been carried out on methods of distinguishing between earthquakes and explosions using recordings at regional distances ($\Delta < 20^\circ$) there are no discrimination criteria making use of such recordings that are yet accepted as being widely applicable. It turns out that earthquakes and explosions are most easily separated given P recorded at teleseismic distances, that is, distances of more than 30° . Then the body-wave magnitude m_b , can be estimated and, given an estimate of M_S from surface waves recorded at any distance, the $m_b : M_S$ criterion (see, for example, Marshall and Basham, 1972) can be used to identify the source: for

a given m_b , explosions have a much lower M_S than most earthquakes. However, there are earthquakes—sometimes called anomalous earthquakes—that generate weak surface waves and on the $m_b : M_S$ criterion look explosion-like. It is in identifying these anomalous earthquakes, that array recordings have proved most useful (see, for example, Douglas *et al.*, 1974a,b). It is for this reason that in what follows most of the discussion is on SP arrays designed to record P at teleseismic distances.

2. Enhancing Seismic Signals in Noise

The use of arrays to enhance seismic signals makes use of the differences in the spatial properties of signals and noise. Ideally the signal at an array would be identical (apart from differences in arrival time) at all seismometers. This is never strictly true, but by restricting the maximum distance between the seismometers of an array to around the largest wavelength of the principal signals of interest, sites can be found where the signal variation is so small that it does not significantly reduce the effectiveness of the array for improving signal-to-noise ratios.

Unfortunately, at some sites the variation in signal shape across the array has turned out to be so great that conventional processing results in loss of signal amplitude. Nevertheless, such recordings can be used for the detection of seismic signals (Ringdal *et al.*, 1975). Processing is carried out on the envelope of the seismograms rather than the seismograms themselves; one way of forming the envelope being to rectify and smooth the seismogram. Such processing has little value for source studies.

To describe how arrays can be used to separate signals from noise, it is usual to represent signals and noise in frequency–wavenumber space. In this representation, array processing can be thought of as wavenumber filtering. A major consideration in designing arrays and processing the data is how they act as wavenumber filters, that is, the filter response as a function of vector wavenumber (see, for example, Birtill and Whiteway, 1965).

White noise that is spatially uncorrelated can be thought of as being uniformly distributed in frequency–wavenumber space. Studies of array recordings show that, provided the separation between seismometers is a kilometer or more, the noise can be assumed to be uncorrelated and random at frequencies above about 1 Hz. At lower frequencies the noise becomes increasingly organized; that is, the noise power is no longer uniformly spread in wavenumber but is concentrated around particular values. The noise is then principally wave trains propagating with well-defined velocities. When a single noise source predominates, as it may do with oceanic microseisms, the noise becomes in effect a coherent signal (see, for example, Douglas and Young, 1981).

Organized noise usually has two components: low-speed surface waves generated at local and regional distances; and body waves with high apparent surface speeds generated at long range (referred to as mantle P waves by Backus, 1966). At sites close to a coast where the noise levels are high, the noise is predominantly the low-speed component and it is only at mid-continental sites, where this component is of low amplitude or absent, that the high-speed noise is seen.

2.1 Delay-and-Sum Processing

The most commonly used method of enhancing signals relative to noise is usually referred to as delay (or shift) and sum: delays are applied to the output of each seismometer (each channel of information) to bring the signals to a common time line, that is, into phase, and the signals are summed with weights n^{-1} , where n is the number of seismometers in the array. The summed signal is often called the array beam.

The noise on the delay-and-sum output is the mean of n numbers (noise amplitudes). If σ^2 is the variance of the noise at the array, then the variance of the mean is σ^2/n , assuming the noise is random and uncorrelated between channels. So the standard deviation of the noise on the sum is $\sigma/n^{1/2}$. If the signal is effectively identical on all channels then it will be almost unaffected by delay-and-sum processing so, as the noise amplitude is reduced by a factor $\sqrt{n}$, the signal-to-noise ratio should show the so-called “root n improvement.” Thus, for example, for signals recorded at YKA (Table 1) root n ($n = 19$) improvement is possible at frequencies above 1 Hz, as shown for the P signal from the Marianas Island earthquake of 16 July 1969 (Figs. 2a and 2b).

The root n improvement shown by Figs. 2a and 2b is obtained only if the SP recordings are filtered to cut out frequencies below about 1 Hz. For the unfiltered SP recordings (Figs. 2c and 2d) the noise reduction is only about a factor of 2 rather than the hoped for $\sqrt{19}$. This shows that the low-frequency noise is correlated between channels and thus that the noise is organized at these frequencies. The failure to obtain root n improvement over the whole SP band for delay-and-sum processing is a problem with all arrays and as a consequence it has become common practice to apply a high-pass filter similar to that applied to obtain Figs. 2a and 2b. This, however, fails to exploit fully the wavenumber filtering property of arrays, the very property for which arrays are installed. For, if the wavenumber of the organized noise is sufficiently different from that of the signal, optimum wavenumber filters can be derived to suppress such noise. The application of such filters seems never to have been investigated for YKA recordings, but examples of optimum filtering of organized noise at another array, EKA, are given in the next section.

The advantage of wavenumber filtering is that it should reduce the need for frequency filtering, which as well as attenuating the noise inevitably distorts the signal. Note, for

FIGURE 2 Delay-and-sum processing of the P waves from the Marianas Islands earthquake of 16 July 1969 (m_b 5.2) recorded at the Yellowknife array. (a) Single channel after application of a 1–4 Hz (causal) bandpass filter; (b) sum after application of a 1–4 Hz (causal) bandpass filter; (c) single channel unfiltered; (d) sum unfiltered; (e) sum (d) filtered with an optimum frequency filter to attenuate noise at around 4 sec period.

example, as shown in Figure 2, that first motion is reduced by such filtering (cf. Figs. 2b and 2d), making polarity and signal onset difficult to measure reliably. Thus, such high-pass filtering should be avoided if possible. If frequency filtering has to be applied then an optimum filter should be used. Figure 2e shows the result of applying an optimum filter of the type proposed by Douglas (1997) to attenuate the low-frequency noise. Although any frequency filter will inevitably remove signal, as well as noise, the use of such an optimum filter clearly minimizes distortion.

Figure 3 illustrates the ability of an array to separate mixed signals. Figures 3a and 3b are longer sections of the P signal from the Marianas Island earthquake than those shown in Figure 2. The single-channel (Fig. 3a) shows no evidence of other arrivals in the signal coda. However, forming the beam to enhance signals from the Nevada Test Site (NTS) shows (Fig. 3c) a second signal—it is in fact P from the NTS explosion ILDRIM—and the Marianas signal is suppressed.

FIGURE 3 Delay-and-sum processing to separate two signals with differing phase velocities using recordings from the Yellowknife array. (a) Single channel showing P from the Marianas Island earthquake of 16 July 1969 (m_b 5.2); (b) sum phased for Marianas Island earthquake (speed 22.1 km sec^{-1} , azimuth 285°); (c) sum phased for speed of 11.8 km sec^{-1} and an azimuth of 183° . Seismogram (c) shows the P signal from the Nevada Test Site explosion ILDRIM (m_b 4.6).

FIGURE 4 The wavenumber response of the Yellowknife array. M is the wavenumber of the signal from the Marianas Islands earthquake at 1 Hz and I that from the NTS explosion ILDRIM. On the delay-and-sum response for the Marianas Islands earthquake, ILDRIM at 1 Hz plots at I' . On the delay-and-sum response for ILDRIM, the Marianas Island earthquake at 1 Hz plots at M' , and for 0.5 Hz at M'' . κ_x and κ_y are the x and y components, respectively, of angular wavenumber in radians km^{-1} .

The wavenumber response for YKA for delay-and-sum processing is shown in Figure 4. Superimposed on the response is the wavenumber at 1 Hz of the Marianas Islands

earthquake (M) and the explosion ILDRIM (I). This shows that if the beam were formed for zero wavenumber (i.e., the sum without time shifts), the 1 Hz amplitude of the earthquake signal would be attenuated by a factor of 2.5 and that of the explosion by about 2. The effect of forming the beam for the earthquake is to move its signal to zero wavenumber so that it is passed unattenuated. The explosion signal at 1 Hz now falls at I' and is predicted to be attenuated by about a factor of 10, and from Figure 3 this could be so. With the array phased for the explosion signal, this signal now lies at zero wavenumber and the earthquake signal at 1 Hz falls at M' . Now it is the earthquake signal that should be attenuated by a factor of ~ 10 . As can be seen from Figure 3c the actual attenuation is only about a factor of ~ 5 . This is because the earthquake signal is not monochromatic with a frequency of 1 Hz: there is clearly a 0.5 Hz component in the signal and for that Figure 4 shows (M'') that the attenuation is only expected to be 5.

The variation in signal shape in the recordings from the individual seismometers of an array is due to scattering at lateral heterogeneities in the crust and upper mantle beneath the array and by the topography at the site. The principal effect of topography is the generation of Rayleigh waves. For, just as a P wave with a curved wave front incident on a plane free surface gives rise to Rayleigh waves—without them the boundary conditions cannot be satisfied—so a plane P wave incident on a nonplanar surface gives rise to surface waves.

One of the best examples of Rayleigh waves generated by a topographic feature is shown by recordings at EKA from earthquakes with epicenters to the north of the array (Key, 1967, 1968). These recordings show arrivals with amplitudes approaching that of initial P and at first sight could be interpreted as a free-surface reflection pP or sP (Fig. 5a). However, summing the array attenuates this arrival (Fig. 5b), showing that its velocity differs from that of P . Investigation shows that the second arrival has a speed of 2.5 km sec^{-1} and an azimuth of 315° (Fig. 5c). The low speed implies that the arrival is a Rayleigh wave, and this is confirmed by the particle orbit, which is a retrograde ellipse. From the speed and azimuth of the surface wave and its arrival time relative to P , it is possible to determine where it was generated: A steep-sided valley, Moffat Water, about 13 km from the array. Rayleigh waves such as that generated by Moffat Water appear large relative to direct P because, although the energy in the waves is small, it is concentrated in a thin zone close to the surface.

2.2 Optimum Wavenumber Filtering

To introduce the principles of optimum wavenumber filtering, consider the use of an array to enhance P signals at zero wavenumber, in noise that has two components, an organized component that is isotropic and has a speed of 3 km sec^{-1} and a frequency of 0.167 Hz—to represent oceanic microseisms with a period of 6 sec—and a random uncorrelated component at all other frequencies. To ensure that the signal is coherent

FIGURE 5 Use of the Eskdalemuir array to identify noise generated by P incident at an irregular free surface. (a) Seismogram recorded by one seismometer of the array showing the P waves (A) from an earthquake in Kamchatka. Note the prominent second arrival (B). (b) Summed seismogram after delay-and-sum processing to enhance signals with the velocity of arrival A (19 km sec^{-1} from azimuth 12°). The arrival B is suppressed, suggesting that it has a different velocity from A. (c) Summed seismogram after delay-and-sum processing to enhance signals with speed 2.5 km sec^{-1} on azimuth 315° . Arrival B is now enhanced and A is suppressed. The low-speed of arrival B indicates that it is probably a surface (Rayleigh) wave.

across the array it is assumed that the maximum separation between seismometers has to be roughly equal to the smallest signal wavelength of interest, say 8 km—the wavelength of a 1 Hz signal with apparent speed of 8 km sec^{-1} .

Now, a plane wave with horizontal wavelength λ will be canceled out by summing the outputs of two seismometers separated by a distance $\lambda/2$ as measured in the direction of propagation. So, as the wavelength of the organized component of the noise is 18 km, a separation of 9 km will enhance signals at zero wavenumber and suppress the oceanic microseisms propagating along the line of the seismometers. Four seismometers at the corners of a square can be used to attenuate microseisms from any azimuth. For such an array, however, the random noise will be reduced only by a factor of $\sqrt{4}$ and can only be attenuated further by increasing the number of seismometers to $n > 4$. If these are to be contained within an overall dimension of $\sim 8 \text{ km}$ then the spacing between some pairs of seismometers will be significantly less than $\lambda/2$, so the noise cancellation achieved by spacing the outer seismometers at around half the wavelength of the 6 sec microseisms is degraded by the additional seismometers.

One way out of this problem is to apply a bandstop filter to the delay-and-sum to remove the oceanic microseisms (and any signals at these frequencies). This gives an estimate of the signal at all frequencies except 0.167 Hz. The noise at these frequencies, being uncorrelated, should be attenuated by $\sqrt{n}$. By bandpass filtering the outputs of the outer four

seismometers to extract 0.167 Hz and forming the delay-and-sum, an estimate of the signal at this frequency can be obtained and added to the delay-and-sum for the other frequencies. In frequency–wavenumber space this procedure modifies the response of the n seismometer array to place a null at the wavenumber of the microseisms. This is optimum wavenumber filtering for a signal at zero wavenumber for this particular noise model and array design.

The optimum wavenumber filtering described above is a special case of the general process of multichannel filtering. In multichannel filtering, each channel is passed through a filter and the filter outputs are summed. In practice, optimum wavenumber filters are estimated by minimizing the mean-square difference between the actual and the desired outputs. The theory for the estimation of such optimum filters is given in a few seminal papers published in the 1960s (see, for example, Burg, 1964; Backus *et al.*, 1964; Backus, 1966; Capon *et al.*, 1967, 1968). To estimate such filters requires the

FIGURE 6 The application of various processing methods for signal-to-noise improvement to the short-period P recordings at the Eskdalemuir array from the earthquake of 21 July 1995 in Gansu Province China (m_b 5.6). (a) Single channel short-period; (b) short-period delay-and-sum; (c) short-period minimum-power output; (d) broadband single channel; (e) broadband delay and sum; (f) broadband minimum power output.

autocorrelation of the noise at each seismometer and the cross-correlations between all possible pairs of seismometers. These correlations can be derived either from a sample of observed noise ahead of the signal or from a noise model such as the simple model used above.

An example of the use of optimum wavenumber filtering of SP recordings from EKA (Table 1 and Fig. 1) is shown in Figure 6a–c. The filters are minimum-power filters, designed to minimize the power on the beam yet pass the signal unchanged, and are derived using a noise model. The details of the model are given by Douglas (1998) and it is similar to that used above, having a random component over the whole range of frequencies covered by the recordings, combined below 1 Hz with an organized component that is isotropic with a slowness of $0.34 \pm 0.05 \text{ sec km}^{-1}$ ($2.56\text{--}3.44 \text{ km sec}^{-1}$). Figure 7 shows signal-to-noise gain as a function of frequency between 0 and 2 Hz. Note that at frequencies below 1 Hz, delay-and-sum processing gives signal-to-noise improvements significantly less than $\sqrt{n}$. Figure 8 shows the wavenumber response for EKA for delay-and-sum and that at 0.2 Hz for the optimum multichannel filters. As expected, with optimum filtering the response is more highly attenuating at the wavenumber of the organized noise than it is for delay-and-sum processing.

FIGURE 7 Noise reductions as a function of frequency $\omega/2\pi$, obtained for the noise preceding P from the 21 July 1995 Gansu, China earthquake. Φ_{DS} is $\{\sigma_{AV}^2(\omega)/\sigma_{DS}^2(\omega)\}^{1/2}$, where $\sigma_{DS}^2(\omega)$ is the noise power on the delay-and-sum output, $\sigma_{AV}^2(\omega)$ is $\sum \sigma_i^2(\omega)/n$ and $\sigma_i^2(\omega)$ is the noise power on channel i . Φ_{MP} is $\{\sigma_{AV}^2(\omega)/\sigma_{MP}^2(\omega)\}^{1/2}$, where $\sigma_{MP}^2(\omega)$ is the noise power on the minimum-power output. Φ_A is Φ_{MP}/Φ_{DS} . ω is angular frequency in radians sec^{-1} .

FIGURE 8 Wavenumber responses for the Eskdalemuir array for (a) delay-and-sum processing, (b) minimum power processing (0.2 Hz). The minimum power filters are those used for processing the 21 July 1995 earthquake in Gansu, China. The shaded area shows where the response is less than 0.2. The inner circle marks the wavenumber equivalent to a slowness of 0.34 sec km^{-1} (a speed of $\sim 2.94 \text{ km sec}^{-1}$). The outer circle is the wavenumber equivalent to a slowness of 0.68 sec km^{-1} (a speed of $\sim 1.47 \text{ km sec}^{-1}$). κ_x and κ_y are the x and y components, respectively, of angular wavenumber in radians km^{-1} .

3. History of Arrays

The arrays, installed in 1960–62, had maximum dimensions of 3–5 km and up to 16 SP seismometers. These arrays were designed to record SP P signals from sources at regional distances. The aperture of such arrays is less than the wavelengths of the signals of interest ($\geq 8 \text{ km}$ at 1 Hz), so initially the processing scheme was simply to sum the signals without time shifts. Such processing enhances signals with high apparent surface speeds from any azimuth but suppresses low-speed and random noise.

In 1960 the United Kingdom began experimenting with arrays. It seems that from the beginning the United Kingdom planned to apply corrections for the time of propagation of the signals across the array. It was assumed that the signal would be coherent over at least a wavelength, so this defined the aperture of the array. The number of seismometers that could be used was limited by the largest number of channels (24) that could conveniently be recorded on the analog magnetic tapes then in use. With 24 channels, 20 channels of data, time, and error correction could be recorded. As initially it was assumed that arrays would be used for recording at regional distances where the wavelength of a 1 Hz signal is $\sim 8 \text{ km}$, the aperture of the first UK arrays was 8–9 km. The first UK-designed array was set up in cooperation with the United States at Pole Mountain, Wyoming (PMW) in 1961, only 10° from the Nevada Test Site (NTS).

Regional arrays are effective, but the PMW recordings revealed that the signals from NTS explosions at such epicentral distances are complex—they differ little from those from earthquakes even though the explosion source should be simpler than that of an earthquake.

In 1962, PMW recorded P signals from the USSR test site in Eastern Kazakhstan and the French test site in southern Algeria. These signals were simple, being principally a cycle or two of large amplitude followed by a low-amplitude coda. Further, it was realized that the amplitude of P decays only slowly between distances of 30° and 90° so that, unless a station can be much closer than 30° to a test site, wherever a station is between 30° and 90° makes little difference to the detection threshold. The United Kingdom then decided to move to recording at teleseismic distances. In the 30° – 90° distance range, apparent horizontal wavelengths range up to 25 km. In consequence, the United Kingdom in cooperation with Canada established in 1963 an array at Yellowknife, Canada (YKA) with an aperture of 25 km. The larger aperture gives YKA a greater resolution for teleseismic P than regional arrays. Two similar arrays that are termed medium-aperture arrays were established as cooperative projects between the United Kingdom and the host countries, at Gauribidanur, India (GBA) and Warramunga, Australia (WRA). Several medium-aperture arrays were also installed by the USSR; an example is the array at Kurchatov (Kim *et al.*, 1996).

When the P signals from these arrays were examined, it was noted that those from earthquakes are often complex; that is, the coda to direct P dies away only slowly and sometimes has amplitude as large as, or larger than, P up to 30 sec after onset. As it appeared that the P signals from explosions are invariably simple, the so-called complexity criterion could be used to identify earthquakes and leave a residue of possible explosions. In one study it appeared that with only one array it was possible to identify up to 90% of the sample of seismic disturbances as definite earthquakes.

One point emphasized in these early studies is that array recordings are required so that the effects of near-receiver scattering can be eliminated and an explosion signal not misclassified as from an earthquake because scattered arrivals make the seismogram appear complex. However, in 1963 the USSR began testing at Novaya Zemlya and it turned out that the signals recorded at YKA from this test site are more complex than is usual for an explosion (Thirlaway, 1966a). The complexity criterion then fell into disuse. However, the differences in form of the P seismograms from earthquakes and explosions are still the basis of some of the most important criteria for recognizing anomalous earthquakes.

The 25 km aperture arrays proved to be remarkably effective for enhancing SP signals and the United States, taking note of this, began to investigate the value of large-aperture arrays. In 1965 the United States opened the LASA in Montana, an array with an aperture of ~ 200 km (see Fig. 1 and Table 1). The data handling for such a large array was an enormous task; two minicomputers were needed simply to receive the data and write it to tape.

Unfortunately, the SP signals turned out to be highly variable across the array, as did noise amplitudes, so $\sqrt{n}$ improvement (~ 23) was never achieved. The signal-to-noise ratio for the beam from the best subarray was often higher than that for the beam for the whole array (Evernden, 1977). There are similar problems with the only other large array ever built, NORSAR in southern Norway.

From 1977 to 1980 negotiations took place between the United Kingdom, United States, and USSR on a Comprehensive Test Ban Treaty. The major component of the proposed verification system at that time was to be stations in each of the three countries. The data from all the stations was to be available to each country. Thus verification that say, the United States was adhering to the treaty would be done mainly using data recorded in the United States. Recordings were thus to be made at regional distances. At these distances the high frequencies in the P signal are less attenuated than at long range and the maximum signal-to-noise ratio is at 2 Hz or above. Ensuring that signals of a few hertz are coherent across the array requires a much smaller array than for recordings at teleseismic distances. Experiments were initiated in Norway on arrays suitable for detecting low-magnitude disturbances at regional distances. The result of this study was the installation of NORESS with an aperture of 3 km (Table 1, Fig. 1).

NORESS has seismometers arranged in concentric rings spaced at log-periodic intervals of radius. This design was chosen to make the array resolution independent of azimuth at which the signals cross the array and maximize the ability of the array to pick out the desired signal and suppress interfering signals (Mykkeltveit *et al.*, 1990). Further arrays of similar design have been installed. Such arrays are to be part of the IMS.

Several arrays of long-period (LP) seismometers have been installed. For example, the LASA had LP seismometers at the center of each subarray. Processing of LP recordings is not as well developed as that for SP recordings, but LP array records have been used to study, for example, the origin of scattered arrivals in the coda of surface waves from earthquakes (Capon, 1970). A few arrays have also been installed to record frequencies over a passband that includes much of the conventional SP and LP recording bands. For example, the four-element BNA array in southern England (Douglas and Young, 1981) has a response that is flat for ground velocity in the band 0.1–5 Hz and the 13-element Grafenberg array (GRF) has a passband from 0.01 to 20 Hz. When the BNA array was installed in the 1970s, the band 0.1–5 Hz was considered to be broadband. However, with the improvements in instrumentation, many recording systems have now been installed that, like the system at GRF, encompasses the whole of the LP and SP passbands, and the term broadband has been extended to cover such systems. Here broadband (or wideband) is used generally for any system that covers at least the conventional SP band and extends down to frequencies of around 0.1 Hz.

4. Arrays for Source Studies

SP arrays were first installed to aid the observation of the first motion of P . This was because if an unambiguous downward first motion was observed, the source would be identified as an earthquake. On this criterion, any disturbances for which only positive first motions are seen might be earthquakes or explosions. Inspection of the delay-and-sum P seismograms recorded at long range then showed the often striking differences in the complexity of earthquake and explosion seismograms (Thirlaway, 1963, 1966a). First motion and complexity differ because of the differences in source mechanisms of earthquakes and explosions and although complexity and first motion as such have fallen out of favor, methods for distinguishing between the two types of source that make use of the form and polarity of arrivals are among the most robust discrimination methods available. Thus, procedures have been developed for testing whether a set of P seismograms are consistent with the generally accepted double-couple model of the earthquake source. Initially the assumption is made that the source is an earthquake at significant depth. The amplitude of P and any possible surface (pP and sP) reflections (which can be in

arbitrary units) is measured, together with the polarity of the phases where these can be observed unambiguously. A search is then made for orientations of the double-couple sources that are consistent with the amplitude ratios, pP/P , sP/P , and sP/pP . If no orientations are found to be compatible with the observed ratios, the source must be assumed to be shallow if all the seismograms are simple, and (in the absence of a clear negative first motion to P) a possible explosion. If there are significant arrivals following P that are inconsistent with a double-couple source, then it is possible that the seismograms are from a series of explosions. For this kind of study it is again essential to have array recordings to ensure that first arrivals and coherent arrivals in the coda are enhanced relative to scattered arrivals and, more importantly, that scattered arrivals are not mistaken for surface reflections. Some of the advantages of using arrays to observe the onset of P are demonstrated by Douglas *et al.* (1997). A detailed discussion on the testing for consistency of amplitude ratios—the relative amplitude method—is given in Pearce and Rogers (1989). Examples of the application of the method to the identification of anomalous earthquakes are given in Pooley *et al.* (1983), Stewart (1987), and Marshall *et al.* (1989) and to the identification of multiple explosions in Clark and Pearce (1988).

The relative amplitude method is most effective if the array stations used are widely spread in azimuth and distance to ensure that the focal sphere is well sampled. Much effort has gone into finding sites for arrays where the noise is below average, and these sites are usually in the middle of continents. This means that the arrays are not well distributed, particularly for sources near the edges of continents and in the southern hemisphere (Pearce, 1996). The effect of choosing low-noise sites has been to make the range of detection thresholds larger. For forensic seismology, any detection may be better than none; but for seismology in general, arrays would be better employed to bring the threshold for noisy stations down toward that of the best stations. At noisy stations where the noise is organized and of low speed, wavenumber filtering can be particularly effective as shown by the example of EKA (Figs. 6 and 7).

The greatest obstacle to source studies is the oceanic microseism peak at around 0.125–0.167 Hz (8–6 sec period). For it is only for large-magnitude sources that signal is above noise over this band. For earthquake source studies, then, it would be better if arrays had been designed to suppress noise in the microseism band and thus to flatten the spectrum of the noise. Then it would be possible to exploit better the full sensitivity of modern seismometers, the outputs from which are currently filtered into the SP and LP bands where the noise has its lowest amplitude and the signal-to-noise ratio is a maximum. Perhaps surprisingly, however, modern recording systems allow wideband signals to be derived from SP recordings by filtering to enhance the low frequencies. At low-noise sites (e.g., YKA) such wideband signals often allow pulse shapes and polarities to be more clearly seen than on the

original SP seismograms even when the wideband signals have lower signal-to-noise ratio than on the original recordings. Such widening of the frequency band can provide information on the fracture processes at the earthquake source as well as aiding in the identification of anomalous earthquakes (see, for example, Douglas *et al.*, 1974a). For noisy sites such as EKA, broadband conversions are usually swamped by noise from the oceanic microseisms, but with wavenumber filtering, as shown by Douglas (1998), these can be reduced significantly. An example of the application of the method of Douglas (1998) to the processing of EKA broadband seismograms derived from the SP recordings is shown in Figs. 6d to 6f. Note that on the broadband seismogram the P , pP , and sP pulses can more clearly be seen than on the SP, so making it possible to estimate a reliable depth.

5. Discussion

The aim of arrays for recording body waves for source studies should be to allow signals to be observed at teleseismic distances from frequencies of a few hertz down as far into the oceanic microseism band as possible. Arrays with apertures of 10 km or more can be used to suppress low-speed noise ($\sim 3 \text{ km sec}^{-1}$), but to suppress mantle P wave noise of around 6 sec period requires arrays with apertures of $\sim 50 \text{ km}$ on sites where the signal is coherent. This raises the question whether it is possible to find a site where 1 Hz is coherent over such large distances. The experience with the LASA and NORSAR suggests it is not. The recordings from these two arrays show that signals are not coherent over more than a few kilometers. However, for the medium-aperture arrays (YKA, GBA, and WRA) the signal is sufficiently coherent over $\sim 20 \text{ km}$ for array processing to be effective at frequencies above 1 Hz. Which sites are the more typical: the highly variable sites of the LASA and NORSAR or those of YKA, GBA, and WRA? There is evidence that there are areas where 1 Hz signals are coherent over large distances (see, for example, Husebye and Jansson, 1966) and this is supported by the similarity of explosion P signals recorded at widely separated stations. So arrays significantly larger than 20 km could be effective in extracting signals from noise. The realization that explosion signals are often simple and similar at long range was one of the first results to come from array studies, and this led Thirlaway (1966b) to coin the term “source window” for the distance range 30° – 90° where observations at good sites give the clearest picture of the source. However, because of the experience with the LASA and NORSAR, the availability of good sites needs to be investigated. Perhaps mobile arrays could be adapted for this kind of experiment. What is required is an array about twice the size of YKA.

Large arrays of the type discussed above—assuming suitable sites can be found—would be ideal for source studies. However, currently the trend is toward the installation of small

arrays to meet the requirements for Test Ban verification in some areas (e.g., former test sites) down to magnitudes well below $m_b 4$. Such low magnitudes can be detected only at regional/local distances. Thus, although the number of arrays will increase with the growth of the IMS, the arrays will be small-aperture and so of little value for extraction of wideband signals.

6. Conclusions

The most effective use of arrays for forensic seismology and seismic source studies in general, at least down to $m_b 4$, is:

1. To widen the frequency band over which signal can be observed above noise.
2. To bring the noise level for recordings at noisy sites down toward that of quiet sites thus increasing the range of distance and azimuth covered by stations recording a given seismic disturbance.
3. To provide from recordings in the distance range 30° – 90° estimates of P signals free from interfering arrivals and thus signals that are best suited for studies of source mechanisms (including distinguishing between earthquakes and possible explosions) and structure in the source region.

The demands of Test Ban verification, however, for regional arrays means that there is no immediate prospect of increasing the number of teleseismic arrays. This is unfortunate: With a few more such arrays, including one or two of large aperture (assuming suitable sites can be found) seismologists would learn much about seismic source processes. Such information, as well as increasing understanding of the earthquake source, might also strengthen further the ability of forensic seismologists to verify the Comprehensive Test Ban—which was the hope when the first arrays were installed all those years ago.

Seismological Methods of Monitoring Compliance with the Comprehensive Nuclear Test Ban Treaty

Paul G. Richards

Columbia University, New York, USA

1. Background

In September 1996, after almost 40 y of negotiations marked by numerous setbacks, the text of the Comprehensive Nuclear Test Ban Treaty (CTBT) was at last agreed and opened for signature at the United Nations. It was signed promptly by all five of the then declared nuclear weapons states—the United States, the Russian Federation, China, the United Kingdom and France—and at the signing ceremony President Clinton called this treaty “the longest sought, hardest fought, prize in nuclear arms control.”

The basic obligations of the CTBT are stated in Article I of the treaty text as follows:

1. Each State Party undertakes not to carry out any nuclear weapon test explosion or any other nuclear explosion, and to prohibit and prevent any such nuclear explosion at any place under its jurisdiction or control.
2. Each State Party undertakes, furthermore, to refrain from causing, encouraging, or in any way participating in the carrying out of any nuclear weapon test explosion or any other nuclear explosion.

The CTBT is intended to prevent non-nuclear-weapons states from proliferating nuclear weapons, and restrains nuclear-weapons states from building weapons more sophisticated than those they now deploy. Although the term “nuclear explosion” is undefined, the CTBT is intended to be a zero-yield treaty. As such, it presents the difficulty that any practical monitoring system based upon detection and identification of nuclear explosion signals can be expected to fail at some low level of yield. The question whether the treaty is adequately verifiable or not is therefore a political–military

judgment in which the merits of banning *all* nuclear testing—which can be confidently monitored above some yield level—have to be weighed against the possibility that small unidentified tests might occur. The verification system must be designed so that tests at yields large enough to have military significance will be identified with high confidence. In this context, we know that crude fission devices of the types used as bombs on Hiroshima and Nagasaki in 1945, with yields around 15–20 kilotons (kt), would be easily detected and identified today. Good verification capability can act as a deterrent to potential treaty violators to the extent that it becomes clear that violations would be detected and identified.

This arms control prize is not yet in hand, however, because although 165 nations had signed the CTBT as of January 2002, the treaty can enter into force only after being signed and ratified by 44 listed countries that operate nuclear power reactors. As of January 2002, 31 of the 44 listed countries had ratified and 41 had signed (the three exceptions being India, Pakistan, and North Korea). India and Pakistan declared their nuclear capability by a series of nuclear tests in May 1998 (see Barker *et al.*, 1998). In October 1999, the US Senate voted not to give its advice and consent to ratification. President Clinton stated strong support of the CTBT and expectation of its eventual ratification by the US—which would require a new and favorable Senate vote—but his successor President George W. Bush has stated opposition to the CTBT, albeit with support for a continued moratorium on US testing.

This record indicates that many political issues surrounding the CTBT remain contentious. Plans are nevertheless going ahead to establish the verification regime, in which seismology plays a key role. Global monitoring for nuclear

explosions is still needed, whether or not the CTBT has entered into force.

This chapter gives general background on test ban monitoring, describes relevant specialized aspects of seismology, and reviews the procedures being developed by the International Monitoring System (IMS) established by the treaty.

All of the most important technical issues in monitoring a CTBT became apparent between 1958, when the so-called "Conference of Experts" was convened in Geneva to see whether agreement could be reached on a verification system, and 1963, when the Limited Test Ban Treaty (LTBT, which banned testing in the atmosphere, the oceans, and outer space) was quickly negotiated, signed, and entered into force. In 1963 there was a perception, influential in some forums, that seismological methods for monitoring underground nuclear explosions were inadequate—a view that helped to prevent the conclusion of a CTBT in this early period (Richards and Zavales, 1996). The text of the CTBT approved by the United Nations in 1996 is about fifty times longer than the text of the LTBT of 1963, in large part because of the extensive provisions (in the 1996 CTBT) for verification. The formal treatment of verification issues in the CTBT will continue to be developed and documented in extensive detail over the next few years. Much of this work will be specified in six different Operational Manuals, mentioned in the CTBT and its Protocol, that will spell out the technical and operational requirements for the following:

- Seismological monitoring and the international exchange of seismological data
- Radionuclide monitoring and the international exchange of radionuclide data
- Hydroacoustic monitoring and the international exchange of hydroacoustic data
- Infrasound monitoring and the international exchange of infrasound data
- The International Data Centre
- On-site inspections.

The IMS seismographic stations send their data to an associated International Data Centre (IDC) for analysis and also, on request, for circulation to National Data Centers. The US National Data Center is the US Air Force Technical Applications Center.

The IMS can be expected to provide data adequate to monitor for underground explosions down to about magnitude 3.5. For explosions executed in the usual way in shield regions without making special efforts at concealment, this corresponds to a yield of around 0.1 kt. However, it is clear from the negotiating record that some countries desired a better monitoring capability. For example, the Geneva working paper CD/NTB/WP.53 of 18 May 1994 stated the US position that "the international monitoring system should be able to . . . facilitate detection and identification of nuclear explosions

down to a few kilotons yield or less, even when evasively conducted, and attribution of those explosions on a timely basis." A few kilotons, evasively tested, could correspond in some cases to seismic signals of about magnitude 3. Assessments as to whether a given monitoring system is adequate for treaty verification, or not, will therefore in practice be driven by perceptions of the plausibility of efforts at treaty evasion.

Up to 1963, when the LTBT was negotiated rather than a CTBT, very few underground nuclear tests had been carried out. Seismographic data then consisted of paper analog recordings from a few hundred stations around the world—data derived almost entirely from earthquakes and chemical explosions—and communications then relied upon standard postal services. But much practical experience in monitoring was acquired following the LTBT, because nuclear explosions were carried out underground at the rate of about one a week for almost thirty years. Yang *et al.* (Chapter 84) list parameters of more than 2000 nuclear explosions conducted in different environments (atmosphere, space, underwater, underground) during the period 1945–1998. A small number (fewer than five) of these explosions were designed to evaluate certain evasion scenarios. At the beginning of a new millennium, seismology is improved in ways hardly imagined in the early 1960s. Thus, seismology today is based upon the operation of tens of thousands of stations, roughly half of them acquiring data that are recorded digitally so that the signals can easily be subjected to sophisticated processing. Such data in many countries are gathered electronically into nationally and internationally organized data centers, for purposes of scientific research and for the study of earthquake hazard and hazard mitigation, as well as for nuclear explosion monitoring. A growing trend since the mid-1980s has been the use of stations equipped with sensors that respond to a broad band of frequencies, with recording systems of high dynamic range so that both weak and strong signals are faithfully documented. Digital seismograms from such systems are now sent to centers from which data segments may be freely accessed by a wide range of users.

The seismic waves of principal interest in CTBT monitoring are the regional phases *Pg*, *Pn*, *Sn*, *Lg*, and *Rg*; the teleseismic phases *P*, *pP*, *pS*, *S*, *sS*, and *sP* (and sometimes *PKP* and *pPKP*); and Love and Rayleigh surface waves. The basic reason for the effectiveness of seismology as a monitoring technology is simply that the different types of seismic sources—earthquakes, explosions (both chemical and nuclear), volcanic eruptions, mine collapses—generate these seismic waves in distinctively different ways. It has therefore been possible to develop objective procedures to identify the nature of the seismic source. The fact that there are so many different types of seismic waves, each with its distinctive characteristics, is on the one hand a burden in explaining the details of monitoring to the many people interested in the subject for policy reasons but not having an interest in seismology *per se*, and on

the other hand the essential key to the effectiveness of seismology as a monitoring tool. Having so many different types of seismic wave, each of which can vary strongly over the distance ranges for which it is observable, means that a great deal of information about the seismic source is potentially available.

An understanding of the terms “regional” and “teleseismic” is essential for an appreciation of the practical problems of CTBT monitoring—and of solutions to these problems. The underlying reason for such a grouping of seismic waves is a property of the Earth associated with a zone of lower velocities and/or lower velocity gradient in the upper mantle, beneath which is a region of higher velocity and/or higher gradients at greater depths. The net effect is that the simplest and most important seismic wave—the first-arriving compressional wave (*P*) traveling downward from the source into the mantle and then back upward—is defocused and thus has low amplitudes at distances within the range about 1000–2000 km from a seismic source. Figure 1 shows schematically the way in which the amplitude of seismic *P* waves at first decreases and then increases as waves propagate to greater distances. Waves beyond about 2000 km are teleseismic, and *P* waves throughout most of this range are simple, having very little change in amplitude with distance out to more than 9000 km.

The compressional waves known as *Pg* and *Pn*, traveling within the crust or just beneath it, are regional in the sense that they do not propagate to teleseismic distances. But the word “regional” here carries the additional implication that such waves are dependent on local properties of the Earth’s crust and uppermost mantle, which can vary quite strongly from one region to another. Regional waves can have large amplitudes (and can thus be easily detected if a seismometer is operated at a regional distance from a source of interest), but they are complex and thus harder to interpret than teleseismic waves. Shear-wave energy can propagate even more efficiently than compressional energy to regional distances. In particular, the largest wave on a seismogram at distances up to 2000 km from a shallow source is usually the *Lg* wave, which consists of shear waves traveling so slowly that they are trapped by total internal reflections within the low-speed crustal wave guide—similarly to the physics by which light can travel to great distances within a low-speed optical fiber. An extensive dataset of seismic signals from a given region must first be acquired and understood before the regional waves from a new event can be interpreted with confidence. (Sometimes, however, the data from a second, more easily accessed region, can be used to aid in the interpretation, if the two regions are known to be geologically similar.)

The key methods of event identification, all discovered too late to have any impact in the early period of CTBT negotiations (1958–1963), entail comparison of the amplitudes of different seismic waves. For example, slow-traveling surface

FIGURE 1 This is a generic illustration of the main differences between regional and teleseismic waves. Seismic wave amplitudes at regional distances are strong near the source, for waves such as *Pg* (propagating within the crust) and *Pn* (propagating mostly just below the crust/mantle interface), but they decrease and can disappear at about 1000 km. Amplitudes increase at around 1700–1800 km, due to the arrival at these distances of the teleseismic *P* wave, which has traveled deeply into the mantle and is less affected by shallow structure. The teleseismic *P* wave varies very little in amplitude out to much greater distances. The reason for the different behaviors of regional and teleseismic waves is the variation in seismic wave speed with depth in the Earth (heavy line, bottom right). The *P* wave speed in average Earth models typically increases from about 5.8 km sec^{-1} at the top of the crust to about 6.5 km sec^{-1} at the bottom, jumping up to a little more than 8 km sec^{-1} at the top of the mantle, beneath which there is often a layer of lower velocities and then at greater depths an increase in velocity with depth. The layer of lower velocities in the upper mantle causes *P* wave amplitudes to be low in a range of distances around 1200–1300 km. The lower section of the figure shows ray paths in the crust and upper mantle. For decades following the LTBT of 1963, when nuclear testing was carried out underground and in-country monitoring was not permitted, monitoring was conducted by National Technical Means (NTM) using teleseismic signals. With the CTBT and the permitted use of in-country stations, attention returned to the study of regional waves since they provide the strongest signals. Regional waves may be the *only* detectable seismic signals, from small-magnitude sources. (Adapted from Romney, 1960.)

waves (Rayleigh, Love), with wavelengths of several tens of kilometers, are generated much more efficiently by shallow earthquakes than by explosions. This result was obtained in academic research in the 1960s (e.g., Brune *et al.*, 1963; Liebermann *et al.*, 1996), became thoroughly documented over the subsequent years (e.g., Lambert and Alexander, 1971), and proved during the era of underground nuclear testing to be a reliable method for discrimination using teleseismic signals for sources down to magnitudes in the range

4–4.5 (Sykes *et al.*, 1983). Over the last 15 years there has been growing recognition that regional *P* waves (such as *Pg* and *Pn*) are often generated much more efficiently by explosions than by earthquakes, in comparison to the excitation of regional *S* waves (such as *Sn* and *Lg*). If signals can be recorded with high enough quality, then the comparison between regional *P* and *Lg* often enables discrimination between earthquakes and explosions to be made at low magnitudes—even lower than magnitude 3 (Hartse *et al.*, 1997; Kim *et al.*, 1997).

2. General Aspects of CTBT Monitoring

This section presents two general points, (1) and (2), and then in (3) describes treaty language on verification and the practical steps such work entails.

(1) An underlying difficulty in treaty monitoring is making the trade-off between simple methods of analysis that are robust, objective, unchanging, and easily explained to people who lack technical training; and those more sophisticated methods which, to a highly trained audience, are demonstrably more effective but that require a greater degree of expert judgment and which will surely change from year to year as methodologies improve. The very existence of so much practical and specialized experience (coming from the decades of monitoring nuclear weapons tests), and of so many seismological resources generating potentially useful data, fundamentally enhances CTBT monitoring capability.

(2) The CTBT will, in practice, be the subject of three types of monitoring, namely:

- That carried out directly by the IDC using data contributed by the IMS
- That carried out by National Technical Means (NTM), i.e., the procedures established unilaterally by various countries using any available information, and all having rights (per CTBT Article IV, ¶34 & ¶37) to use objective information from NTM as a basis for requesting an on-site inspection
- That carried out by numerous private or national organizations, each acquiring and/or analyzing data of some relevance to CTBT monitoring.

The third of these types of monitoring, associated with what the CTBT (Article IV, ¶27 & ¶28) calls supplementary data, is more nebulous than the other two types, but can nevertheless be important, for example, in confidence-building measures and as a source of much basic information and many skills needed by the IMS and IDC. Vast regions of North America, Europe, the Western Pacific, and parts of Central Asia, Northern and Southern Africa, and the Middle East are now being monitored closely for earthquake activity

down to magnitude 3 or lower by organizations whose data and methods of analysis are freely available. It is from this type of earthquake monitoring, and from field programs to study the structure of the crust and uppermost mantle, that the broad seismological community has acquired its knowledge of regional wave propagation; and familiarity too with the differences between seismic signals from earthquakes and from blasting associated with the mining, quarrying, and construction industries. Seismology is still a growing science, likely to be driven indefinitely by the need to understand and mitigate earthquake hazards. Individual earthquakes can still kill many thousands of people, and they are one of the few catastrophic phenomena capable of matching the trillion dollar levels of damage that a single nuclear weapon can inflict. It can hardly be emphasized too much that explosion monitoring for the CTBT will be greatly improved in the long term by cross-fertilization between the earthquake monitoring and explosion monitoring communities.

(3) The main part of the CTBT dealing with verification is Article IV, of which ¶1, in its entirety, reads as follows:

In order to verify compliance with this Treaty, a verification regime shall be established consisting of the following elements:

- (a) An International Monitoring System;
- (b) Consultation and clarification;
- (c) On-site inspections; and
- (d) Confidence-building measures.

At entry into force of this Treaty, the verification regime shall be capable of meeting the verification requirements of this Treaty.

Then follow 67 more paragraphs with details on verification. The treaty Protocol further spells out details of the IMS and IDC functions and procedures for on-site inspections, and in an Annex lists the location of 321 IMS stations that are to acquire seismic, radionuclide, hydroacoustic, and infrasound data in support of the treaty.

The work of monitoring for underground nuclear explosions using seismological methods entails the following separate steps:

- Detecting seismic signal.
- Associating into a single group the various seismic signals that are generated from a common seismic source.
- Estimating the location of that source, and the uncertainty in the location.
- Identifying the seismic source (whether earthquake or explosion), together with estimating the source size. The role of the IMS, vis-à-vis identification, is that of “Assisting individual States Parties . . . with expert technical advice . . . in order to help the State Party

concerned to identify the source of specific events” (CTBT Protocol, Part I, ¶20(c).) The responsibility of identification is left to each State Party, but the IDC assists by carrying out a process called event screening, described further, below.

- Seismology also plays a role in on-site inspections and in confidence-building measures.

It follows that much work of the IMS and IDC focuses on the development of routine procedures for data acquisition and data analysis of all detected events. But historically it is known that monitoring for nuclear explosions results in the need, in practice, to pay special attention to what are called “problem events,” which by definition are events that are detected but that cannot be unambiguously identified routinely as not being nuclear explosions. Such problem events can become targeted for special efforts in the acquisition of additional data, and for the execution of additional data analysis. Care will be needed in spelling out appropriate procedures for addressing problem events, since, by their very nature, singling out a detected event as a problem (requiring more than merely routine analysis) entails a preliminary effort to identify the event—which is not an IMS function. Instead, the IMS can carry out event screening, entailing the use of standard procedures to measure agreed-upon parameters that are helpful for characterizing whether an event is a nuclear explosion or a chemical explosion or an earthquake. Different countries will likely reach different conclusions on how to treat a problem event, given the territory on which the event appears to be located, and given the possible predisposition of one or more State Parties to believe that serious efforts might somewhere, someday, be taken to conceal a small nuclear explosion. For example, much has been written on the possibility (or impossibility) of masking a nuclear explosion with a large chemical explosion, and/or reducing its seismic signals by carrying out the nuclear explosion secretly in a large underground cavity that has been sealed to prevent the escape of radionuclides. We may note Article II, ¶51 of the CTBT, which states (with reference to the Technical Secretariat) that “The Director-General may, as appropriate, after consultation with the Executive Council, establish temporary working groups of scientific experts to provide recommendations on specific issues.” However, if problem events arise with great frequency, an advisory group convened to deal with them could be overwhelmed. Only time will tell how much of the work of attempting to identify problem events will be done by the IMS and the IDC and how much will be done by States Parties, which can receive IMS data at their National Data Centres (NDCs) as well as having access to their own National Technical Means.

With the above items (1)–(3) as background, let us now turn to brief reviews of the specific steps that must be taken in CTBT monitoring by seismological methods.

3. Technical Issues Arising in Routine Monitoring

3.1 Detection of Seismic Signals

The CTBT Protocol lists 50 sites around the world at which either a three-component seismographic station or an array of seismometers is to be operated, sending uninterrupted data to the International Data Centre (IDC). It is generally understood that this is a digital datastream, available at the IDC in near real time. These 50 stations constitute the primary network, deployed at sites indicated in Figure 2. Much experience is now available from a network of similar size, operated since 1 January 1995 initially as part of the Group of Scientific Experts Technical Test #3 (GSETT-3, carried out under the auspices of the Geneva-based Conference on Disarmament, which negotiated the text of the CTBT), and later under the Comprehensive Test Ban Treaty Organization, headquartered in Vienna. The GSETT-3 IDC, based near Washington, DC, USA became the Prototype IDC (PIDC) shortly after the CTBT was opened for signature in 1996, and served for five years as the testbed for many procedures that were taken up by the Vienna-based IDC in February 2000.

For seismic sources whose signals are detected by the primary network, and for which the location estimate and other attributes of the source are likely to be better quantified if additional signals are acquired, the CTBT Protocol lists an additional 120 sites around the world at which either a three-component seismographic station or an array is to be operated. These stations, constituting the auxiliary network with locations shown in Figure 3, are to operate continuously; but their data is to be sent to the IDC only for time segments that are requested by a message from the IDC. Much experience with such an auxiliary network, of somewhat smaller size, has now been acquired during GSETT-3 and later by the PIDC.

More than half of the 50 primary stations, and some of the 120 auxiliary stations, are listed in the CTBT as operating an array. A seismographic array consists of a number of separate sensors, typically between about 10 and 30 with short-period response, spaced over a few square kilometers or in some cases over tens of square kilometers, and operated locally with a central recording system (see Chapter 23, Douglas). Array data can be processed by introducing a system of signal delays at each sensor and then signal summation, to improve the strength of coherent signals and to reduce the incoherent noise. The resulting improvement in signal-to-noise ratio enables a single array to detect teleseismic signals approximately down to m_b 4–4.5 (Jost *et al.*, 1996), and significantly lower in the case of some well-sited arrays. From the detection of slight differences in the arrival time of a particular seismic wave at the different sensors, it is possible to infer both the azimuth and the horizontal slowness of the arriving signal. IMS array stations also have at least one three-component broadband sensor.

FIGURE 2 Map showing the location of IMS primary seismicographic stations (circles and triangles). All these stations are to include at least one three-component broadband instrument. Filled symbols are for stations contributing data in near real time as of July 2000; open symbols are for proposed stations. Triangles indicate stations that operate only a three-component sensor; circles, indicate stations that also operate arrays of short-period vertical sensors. Forty-nine primary stations are shown; the location of one more station is to be decided.

FIGURE 3 Map showing the location of 119 IMS auxiliary seismicographic stations, which contribute their data on request to the International Data Centre; the location of one more station is to be decided. Symbols, are as in Figure 2.

What, then, is the expected detection threshold of the CTBT primary seismographic network? (Note that the auxiliary network does not contribute to the IMS detection capability.) For detection of enough signals to provide some type of location estimate, GSETT-3 was planned (CD/1254) to have a threshold detection capability in the magnitude range below 3 for large parts of Eurasia and North America. (It was above magnitude 3.4 in some continental areas of the southern hemisphere, and above magnitude 3.8 in parts of the southern oceans.) The design capability of the CTBT primary network has not been specified. In practice, however, the CTBT 50-station primary network appears capable of providing detection at three or more stations for at least 90% of events with $m_b \geq 3.5$, for almost all of Eurasia, North America, and North Africa. In certain areas, which include the former test sites in Nevada for the United States and in Novaya Zemlya for the Russian Federation, the IMS seismographic network is essentially complete, and detection capability is typically below magnitude 2.5. The IMS station nearest to the Chinese former test site at Lop Nor is an array at Makanchi, Kazakhstan, which began operations in mid-2000 and which can be expected to provide detections down to low magnitudes for Western China.

From January 1995 to February 2000 when operations transferred to Vienna, the stations operating under the auspices of the CTBTO grew from about one-half up to two-thirds of the intended 50-station IMS primary network, and reached about one-half of the intended 120-station IMS auxiliary network. During this five-year period, the PIDC made available (at <http://www.pidc.org>) a number of reports of global seismicity derived from the primary and auxiliary networks. The most important report is the daily Reviewed Event Bulletin (REB), typically published three to five days in arrears, listing the events that have occurred that day, including location estimates, magnitudes, a map of the reporting stations for each event, and arrival times of detected phases at these stations. About 50 events have been reported each day on average, with some wide variations, for a total of about 100 000 events included in the REB over its first five years. The production of reviewed bulletins has to be done for all four monitoring technologies used by the IMS (seismology, hydroacoustics, infrasound, radionuclide monitoring), but for the foreseeable future the most highly developed and most important of these technologies is seismology, and almost all of the events reported each day by the IDC are earthquakes and mining blasts.

The transfer of IDC operations to Vienna in February 2000 became associated with a significant change in practice, namely, that the daily Reviewed Event Bulletin and the seismographic and other data upon which it is based, ceased to be made openly available to the research community, as had been the case during operations under GSETT-3 and by the PIDC. The IDC makes the REB and all IMS data available to National Data Centres, but data can then be subject to Article II, ¶7: "Each State Party shall treat as

confidential and afford special handling to information and data that it receives in confidence from the Organization in connection with the implementation of this Treaty." Many voices have been raised in support of a return to open availability of IMS data and IDC data products such as the REB, for example, on grounds that the CTBT itself states in Article IV, ¶10, that "the provisions of this Treaty shall not be interpreted as restricting the international exchange of data for scientific purposes." The quality of IDC operations and products will be greatly enhanced in the long term by having a diverse community of data users. Such users find problems with station calibration, occasional mistakes in the REB and other data products, and continually provide suggestions for improvement, in this way promoting a higher level of monitoring operations at the IDC. Many States Party, including the United States, have indicated their position that all IMS data should be made openly available without delay.

In subsections that follow, further detail is given on the work of seismic signal association, on making seismic location estimates, and on seismic event screening, as carried out by the International Data Centre.

3.2 Association of Signals

Each year, somewhat more than 7000 earthquakes occur with magnitude $m_b \geq 4$; and about 60 000 earthquakes occur with $m_b \geq 3$. While chemical explosions with $m_b \geq 4$ are rare (a few per year, if any), there are probably on the order of a few hundred worldwide at the $m_b \geq 3$ level, and many thousands per year at smaller magnitudes that are detectable at stations close enough. The problem then arises of sorting through the tens of thousands of signals each day that will be detected at a large data center from analysis of array data and three-component station data; and collecting together all the signals that are associated with the same seismic source. This has been a major computational problem of the GSETT-3 IDC, since seismic sources with $m_b > 4$ typically generate more than one detection at many IMS stations (for example, detection of P , pP , PKP , S , SS , Love, and Rayleigh waves), and the detections from different events can overlap in time at each station. Effective methods of sorting through the interspersed detections have been found, but in practice 40% or more of the detections recorded on a given day remain unassociated. In the work of assembling sets of detections common to the same event, array stations in principle have the advantage, over three-component stations, of permitting determination of the direction of the source from a station at which there is a detection. An array can even indicate two or more different source directions from which signals arrive at the array at about the same time. However, in practice, automated determinations of the azimuth of signal arrival can often be inaccurate. While the azimuth estimate may be useful for association purposes, it is typically not used in event location.

3.3 Location of Seismic Sources

The CTBT Protocol, Part II, ¶3, states that

The area of an on-site inspection shall be continuous and its size shall not exceed 1000 square kilometers. There shall be no linear dimension greater than 50 kilometers in any direction.

This condition presents a challenge for those at the IDC, who may have to estimate the location of an event that could become the basis of an on-site inspection request. The challenge is especially difficult for small events, when the estimate may have to be based upon regional seismic waves alone.

Note that accurate location estimates are needed not only for events destined to be considered for on-site inspection. They are needed for essentially *all* the events for which a set of detections can be associated, since in practice an interpretation of the location (including the event depth) is commonly used for screening at the IDC, and perhaps for rapid identification by NDCs. It can be crucial to know whether an event is beneath the ocean, or possibly on land; whether it is more than 10 km deep, or possibly near the surface; whether it is in one country or another. One of the first statements of failure to meet these technical challenges was given by North (1996), reporting on GSETT-3 after about 20 months of REB publication:

Many of the events listed in the (REB) are poorly located. The 90% confidence ellipses exceed 1000 sq. km for 70%, and 10000 sq. km for 30%, of all REB events. Furthermore, comparison by various countries of the locations produced by their own denser national networks with those in the REBs show that the REB 90% confidence ellipses contain the national network location less than half of the time... One feature... that is particularly troublesome is that many events will be recorded only at teleseismic distances, and that few will be recorded only to regional (< 2000 km) distances. Thus an appropriate means of implementing path-dependent teleseismic travel times, and of transitioning from these to regional travel time curves, will need to be developed.

After more than five years of REB publication, the same problems were still to be found: purported 90% error ellipses were often much larger than 1000 km², they did not include true locations 90% of the time, and depth uncertainties did not adequately represent errors in depth.

It is important to understand why REB location estimates using conventional methods have been so poor, since the error in measuring the arrival time of seismic waves is usually less than one second (and is usually less than 0.1 sec when signal-to-noise ratios are good); and the speed of seismic waves is less than 10 km sec⁻¹ in the Earth's outer layers where the events of interest occur and where the measurements are made. It would therefore appear that seismic

sources can routinely be located to within a few kilometers, and with an areal uncertainty much less than 100 km². In principle this conclusion is valid; nevertheless, it does not apply using conventional methods of event location, because these are not based upon a sufficiently good model of the Earth's velocity structure. It is the model errors, not the pick errors, that currently dominate the resulting location errors, at least for events larger than about m_b 4. (For smaller events, the pick errors can be comparable to model errors.) The overall goal of improving locations for events larger than m_b 4 based on seismic arrival times can be achieved only by reducing the effect of model errors.

At depths greater than about 200 km, the Earth's velocity structure is known quite accurately (i.e., to well within 1% at most depths, the biggest exceptions being in regions of subducting lithospheric plates and at certain places just above the core-mantle boundary). The main difficulty is at shallower depths, i.e., within the crust and uppermost mantle, where the actual speed of seismic waves may differ in unknown ways, sometimes by as much as 10%, from the velocity that we often assume (such as that given by *iasp91* or some other standard Earth model). The actual Earth also has nonhorizontal interfaces, which are not allowed for in simple Earth models, and which can affect the azimuth of an arriving signal. In summary, the measured arrival times and directions of teleseismic waves are influenced in unpredictable ways by unknown Earth structure. But the arrival times and directions of regional waves, which depend much more strongly on shallow structure, can be even more variable than teleseismic waves. For example, if a seismic event is actually 1000 km from an IMS station and generates a regional wave that is detected at the station, and if the arrival is interpreted with a speed that is wrong by 5%, then the event will be estimated from that observation alone as having originated at a distance that is incorrect by about 50 km.

When estimating event locations and their uncertainty, there are essentially only three ways to get around the practical problem of ignorance of Earth structure (i.e., model error): (a) by using numerous stations at different azimuths around the source and thus averaging out the effects of the difference between the Earth's actual velocity structure and that of the model (which traditionally has been taken as a 1D distribution in which velocity depends on depth alone); (b) by building up information about the Earth's velocity structure and thus finding a more sophisticated and significantly more accurate 3D model with which to interpret arrival times; and (c) by "calibrating" the station (or array), so that in effect the source of interest is located with reference to another event, whose location is known accurately, and which preferably is not far from the source of interest. In this latter approach, the data for the unknown event is the difference in arrival times for the two events, as recorded at each station. From such data, we can often estimate accurately the difference in location between the known and unknown locations,

and hence estimate the unknown location. Equivalently, for enough calibration events, and using appropriate methods of smoothing, one can use empirically determined travel times for each seismic wave from each potential location to each station. The monitoring community now refers to seismic events whose location is known to within, say, 5 km, as “GT5” events (GT standing for “ground truth,” the accurate location information coming, for example, from a local seismographic network, or from field observations of ground rupture in the case of a shallow earthquake, or from special efforts to record the location and origin time of mine blasts).

The USGS and the International Seismological Centre (ISC) rely upon (a) for routine processing, for then the effect of using an incorrect Earth model is reduced. The research community uses one or more of (a), (b), or (c) but only in studying special sets of events, restricted to very limited regions. The IDC cannot use (a) except for large events since the REB is based on IMS stations alone, and for events below m_b 4 only a small subset of IMS stations provide detections. The IDC is therefore beginning to use methods (b) and (c). But even with great efforts based on hundreds of special studies, we will not know the Earth’s 3D shallow structure adequately on a global scale for decades, ruling out reliance on (b) alone in the short term, though this method can be used successfully for some regions. This leaves (c), based upon ground truth events in the region for which accurate location capability is required, as the most important short term method. The IDC is likely to be the first organization to publish location estimates, on a global scale, using travel-time curves tailored individually for each station in the network from which the bulletin is prepared. The method will succeed to the extent that GT events of sufficient quality and quantity can be found to calibrate IMS stations. Ideally, one would like to have numerous GT0 events for calibration purposes all over the world. In practice, GT5 events or in some regions GT10 events may be the best that are available.

To conclude this section with a practical example of a day with a typical number of seismic events, Figure 4 shows the location of 58 events reported in the REB for 11 May 1998. One of these events was the nuclear test carried out by India, and announced as consisting of three near-simultaneous nuclear explosions. This test of course attracted headlines, though from the monitoring point of view the initial work of association and event location was done by the PIDC in just the same way as for 57 other events that day. In 1998, event location was based upon interpretation of arrival times using the *iasp91* model of the Earth. For the Indian event, 62 stations provided detection of 86 different arrivals, and this event was well-located because of the numerous stations that contributed data—see (a) above.

3.4 Identification of Seismic Sources

Once the detections from a seismic event have been associated and an accurate location estimate has been obtained, the

next step in monitoring is that of event identification. A review of the best technical methods for carrying out this step is given, for example, by a report of the Office of Technology Assessment of the US Congress (1988). But the actual identification of an event as possibly being a nuclear explosion and hence a treaty violation, perhaps warranting a request for an on-site inspection, entails judgments that bring in political as well as technical assessments. Therefore, as noted above, the IDC’s role in event identification is limited to providing assistance to states party to the treaty, rather than actually making an identification. Further detail is given in Annex 2 to the CTBT Protocol, which indicates that the IDC may apply “standard event screening criteria” based on “standard event characterization parameters.” To screen out an event, means that the event appears *not* to have features associated with a nuclear explosion. The underlying idea is that if the IDC can screen out most events, then states party to the treaty can focus their attention on the remaining events. For example, an event may have its depth estimated with high confidence as 50 km. Such an event would be screened out, by a criterion that “events confidently estimated as deeper than 10 km are not of concern.”

For events detected by the IMS seismographic stations, Annex 2 lists the following parameters that may be used, among others, for event screening:

- Location of the event
- Depth of the event
- Ratio of the magnitude of surface waves to body waves
- Signal frequency content
- Spectral ratios of phases
- Spectral scalloping
- First motion of the *P* wave
- Focal mechanism
- Relative excitation of seismic phases
- Comparative measures to other events and groups of events
- Regional discriminants where applicable.

There is an extensive literature on how each of these characteristics can help to achieve event identification, but it will take a number of years to develop detailed objective criteria in the context of IMS event screening. For the present chapter, a few examples must suffice to demonstrate how methods of identification may become the basis of standard screening by the IDC. Thus, one of the most successful discriminants is based on comparison of the magnitude m_b , measured from the amplitude of short-period *P* waves, and the magnitude M_s , measured from the amplitude of long-wavelength surface waves. As mentioned above in Section 1, this discriminant was discovered in the 1960s. It exploits the fact that shallow earthquakes are far more efficient than nuclear explosions in exciting surface waves, for events with comparable *P* waves. As a preliminary result from studies at the

FIGURE 4 The Reviewed Event Bulletin for 1998 May 11 contained 58 seismic events, of which the 27th was an Indian nuclear test. Shown here is a map and list of these event locations. Larger circles on the map indicate larger magnitudes. (Obtained from <http://www.pidc.org>.)

FIGURE 5 The $M_S:m_b$ discriminant, in practical application, depends upon the particular details of how seismic magnitudes are defined. Here are shown magnitudes for 1226 shallow events in the REB, presumed to be earthquakes, in which m_b has been assigned after making corrections for station magnitude bias with respect to network-average m_b values. Three nuclear explosions are included, and a screen that removes events for which $M_S \geq 1.25m_b - 2.45$ is very effective in removing a large fraction of the shallow earthquakes and none of the nuclear explosions. (Adapted from work of David Jepsen and Jack Murphy.)

PIDC, Figure 5 shows that a large percentage of shallow events (but no nuclear explosions, in this example) may be successfully screened out if they have $M_S \geq 1.25m_b - 2.45$.

Another screen, conceptually even simpler, is one based upon depth estimates, recognizing that depths greater than 10 km are in practice inaccessible to human activity, including nuclear testing. Events can thus be screened out if (a) their depth estimate is greater than $10 \text{ km} + 2\sigma_D$, where σ_D is the variance of the depth estimate; and (b) certain criteria are met, to ensure that elementary mistakes have been avoided in making the depth estimate. In work at the PIDC, a conservative approach has been taken to ensure that events that appear to be deep, in terms of interpreting their P and S arrivals, have additional depth indicators (such as surface reflections pP and sP , and significant changes in the time interval between P and pP with increasing distance). The preliminary result is that about 20% of events with magnitude ≥ 3.5 are screened out by a combination of (a) and (b) (D. Jepsen, paper presented at a DTRA-sponsored workshop, Kansas City, June 2000). It is to be hoped that this percentage will rise significantly if more precise estimates of depth can be made with confidence. Note too that discriminants often work well in combination, so that, by making

better depth estimates, one can expect to reduce the number of deep events (say, in the range $\geq 50 \text{ km}$) that have to be subjected to the $M_S:m_b$ screen. Such a reduction would help the latter discriminant perform better (i.e., increase the separation between earthquake and explosion populations), since deep earthquakes are less efficient in exciting surface waves and tend to look more explosion-like in an $M_S:m_b$ diagram.

Depth estimates, and measurements of m_b and M_S , can be based upon teleseismic waves. In practice it is important also to develop discriminants, and their specific application as screens, for events too small to be well characterized teleseismically. One example is the use of high-frequency spectral ratios of P and S regional waves (such as Pn/Lg ratios). Hartse *et al.* (1997) and Kim *et al.* (1997) have shown in practice that such ratios are abnormally high for small underground explosions as compared to shallow small earthquakes, and this discriminant can be applied successfully down to magnitude 3 and possibly even smaller. The preliminary result is that more than 60% of events with magnitude ≥ 3.5 are screened out on the basis of their P/S spectral ratios (D. Jepsen, paper presented at a DTRA-sponsored workshop, Kansas City, June 2000). In practice, objective screening based upon such a discriminant may be developed over a period of time and routinely applied at the IDC in ways that may have to be fine-tuned slightly differently for different regions.

Below magnitude 4, mine blasting can result in seismic events detected and located by the IDC that appear similar to small nuclear explosions using criteria such as depth estimates, weak surface waves, and high P/S spectral ratios. Hedlin *et al.* (1989), Kim *et al.* (1994), and others have found characteristic spectral interference patterns for such events, based presumably on the fact that commercial blasts routinely consist of numerous small explosions that are fired in a sequence of delays. The resulting seismic source is therefore somewhat spread out in space and time. Another potential discriminant of mine blasting is the infrasound signal that can be generated by such sources (Hagerty *et al.*, 2002), and which would not be expected from a small underground nuclear explosion unless it vented significantly—which, in turn, would likely result in a characteristic radionuclide signal. New discriminants for particular types of small seismic events continue to be developed, both in field projects with specially deployed monitoring equipment, and in subsequent adaptation for candidate screening methods to be applied at the IDC to IMS data.

In addition to widely applied screens based upon m_b and M_S and upon depth, more specialized screening desired by a particular State Party may be carried out by the IDC as described in the Protocol, Part I, ¶21:

The International Data Centre shall, if requested by a State Party, apply to any of its standard products, on a regular and automatic basis, national event screening criteria established by that State Party, and provide the

results of such analysis to that State Party. This service shall be undertaken at no cost to the requesting State Party.

4. Evasion Scenarios

If a nuclear explosion is conducted deep underground (depth around 1 km) at the center of a large spherical cavity in hard rock, with radius greater than or equal to about 25 m times the cube root of the yield in kilotons, then the seismic signals can be reduced by a so-called decoupling factor that may reach up to about 70, i.e., by almost two magnitude units. It is easier to build cavities of the same volume that are elongated rather than spherical, and apparently such aspherical cavities can also achieve high decoupling factors, but they can also increase the concentration of stress on the cavity and make it much more likely that radionuclides will be released into the atmosphere and detected by the radionuclide monitoring network of the IMS. An overall evaluation of the cavity decoupling scenario therefore raises a number of different technical issues:

- Does a country considering an evasive test have access to a suitably remote and controllable region with appropriate geology for cavity construction?
- Can the site be chosen to avoid seismic detection and identification (recognizing that seismic events are routinely reported down to about magnitude 3 by earthquake monitoring agencies for many areas in industrialized countries, and that many countries routinely monitor neighboring territory)?
- Can cavities of suitable size and shape and depth and strength be constructed clandestinely in the chosen region, with disposal of the material that has to be removed from below ground?
- Can nuclear explosions of suitable yield be carried out secretly in sufficient number to support the development of a deployable weapon? (This question covers numerous technical issues, including the ability to ensure the yield will not be larger than planned; and to keep all yields of a test series large enough to learn from, yet small enough to escape identification.)
- Can radionuclides be fully contained from a decoupled explosion?

Each of these questions has been the subject of extensive technical analyses.

My own opinion is that it is technically possible to address a few of these issues in a clandestine program in isolation from the others, but that mastery of all these issues combined could not be achieved except possibly by a full-blown multi-billion dollar effort by a nation that already had practical experience with underground nuclear testing. Such a nation would have little to learn technically, much to lose politically,

and the treaty evasion program would still be at great risk of discovery since multibillion dollar efforts intrinsically attract attention in the modern world.

Another evasion scenario is the use of mining operations and large chemical explosions to mask or disguise an underground nuclear explosion. There is a limit on the yield of any nuclear explosion that could be hidden in this way. Chemical explosions are almost always delay-fired at shallow depths, so they are inefficient in generating seismic signals, relative to nuclear explosions that are tamped (Khalturin *et al.*, 1998). It therefore appears that only mines with the largest blasting operations are conceivable candidates for hiding militarily significant efforts at CTBT evasion.

There are two types of technical effort that can be carried out to help monitor mining regions for compliance with a CTBT. The first of these is installation of nearby seismographic stations that record digitally at high sample rates. The purpose would be to provide high-quality data that can distinguish between single-fired explosions and the multiple-fired explosions typical of mining operations. The second is provision of technical advice to mine operators so that they execute their blasting activities using modern methods of delay-firing—which have economic advantages, as well as enabling the blasting of rock in ways that do not make the large ground vibrations (and strong seismic signals) typical of old-fashioned methods of blasting.

Addressing the reality of how the IMS and States Party will handle large blasting operations—or the occasional single-fired chemical explosion (whose seismic signals may indeed look just the same as those of a small nuclear explosion), the CTBT Article IV, ¶68, states that

In order to ...[c]ontribute to the timely resolution of any compliance concerns arising from possible misinterpretation of verification data relating to chemical explosions ... each State Party undertakes to cooperate with the Organization and with other State Parties in implementing relevant measures ...

These measures are spelled out in the Protocol, Part III. They provide, on a voluntary basis, information on single-fired chemical explosions using 300 tons or more of TNT-equivalent blasting material; and information on mine blasting (such as mine locations) for all other chemical explosions greater than 300 tons TNT-equivalent.

To the extent that mine blasting remains a serious concern, problems can be addressed with nearby installation of infrasound and radionuclide monitoring equipment, and with site visits. These activities would be voluntary under the CTBT, but they could also be made the subject of bilateral agreements.

For a suspected nuclear test, the CTBT contains extensive provisions for on-site inspection, at the request of a State Party and with at least 30 affirmative votes of the 51-member Executive Council of the CTBT Organization.

Some remarkable assessments of evasion scenarios were presented in the US Senate debate of October 1999, leading up to the negative vote on CTBT ratification. Thus, the Senate majority leader stated in executive session that

A 70-kiloton test can be made to look like a 1-kiloton test, which the CTBT monitoring system will not be able to detect.

He was referring to the decoupling scenario. Treaty opponents gave speeches which included exactly the same sentence:

While the exact thresholds are classified, it is commonly understood that the United States cannot detect nuclear explosions below a few kilotons of yield.

It was also stated that

Advances in mining technologies have enabled nations to smother nuclear tests, allowing them to conduct tests with little chance of being detected.

Let us address each of these three statements in turn.

Seventy kilotons would be an enormous explosion, about twice the energy of the combined Hiroshima and Nagasaki bombs, and would indeed be of military significance. The cavity that conceptually might reduce signals from a test of this size to something comparable to 1 kt would have to be deep underground (on the order of 1 km deep), with volume equal to that of a sphere 200 m in diameter. Such a spherical cavity could not be built in practice, not even in the open, let alone in secret. Just supposing it could be built, almost all the 70 kt energy released by the test would go into pumping up gas in the cavity to about 150 times normal atmospheric pressure. These gases would be radioactive, and the high pressure means they would leak through cracks that inevitably would exist in the 125 000 m² or more of cavity wall even if the cavity did not collapse. Distant radionuclide sensors of the IMS would detect the test if only 0.1% of the radioactivity escaped. The small fraction of energy released as seismic signals, if comparable to those from a typical (well-coupled) 1-kt test, would travel far beyond the rock surrounding this hypothetical (impossible-to-construct) cavity, and would be large enough for detection at numerous seismometers all over the world, including those of the CTBT monitoring system.

As for the United States not being able to “detect nuclear explosions below a few kilotons of yield,” this might have been an accurate representation of the state of affairs in about 1958 when CTBT negotiations began. But it is now more than 40 years later. Unclassified arrays of seismic instruments continuously and routinely monitor vast areas of the globe for earthquakes and explosions down to low seismic magnitudes, reaching down to about magnitude 2 at Russia’s former nuclear test site on Novaya Zemlya. This capability translates into the ability to detect down to about 0.01 kt of well-coupled yield.

As for mining technologies, the overall trend of modern methods of mine blasting has resulted in general in smaller seismic magnitudes than were prevalent a few decades ago. There are only a limited number of mining regions where signals from a small (~ 0.1 kt) nuclear test could be masked by a simultaneous mine blast without taking the additional steps of putting the nuclear test in a cavity—which would be associated with the complications listed above.

To summarize this section: If concern over evasion scenarios is sufficient that problems are targeted for resolution, then the goal of “monitoring . . . nuclear explosions down to a few kilotons yield or less, even when evasively conducted” (the US position quoted in CD/NTB/WP.53 of 18 May 1994) is achievable.

5. Concluding Remarks

The work of monitoring the CTBT by seismological methods will be demanding, because of the technical difficulty and the scale of organizational effort that is necessary, and because of the need to interact with political and bureaucratic decision making. Evaluations of CTBT monitoring capability may be carried out as part of the domestic ratification process in each of the different signatory states. Such evaluation during the US Senate debate of 8, 12–13 October, 1999 relied upon a series of unsupported assertions. Evaluations are carried out from time to time, together with budgetary review, by government agencies, not all of which are eager to put resources into a major initiative in nuclear arms control. A review of nuclear explosion monitoring has not been carried out in the US political arena since the 1980s (US Congress, 1988).

It may be noted that there is an ongoing need to monitor all environments for nuclear explosions, regardless of whether the CTBT ever enters into force. The IMS and IDC therefore have an important role in global and national security, independent of the treaty’s status.

The work of treaty monitoring is enhanced by the existence of major seismological resources other than the IMS primary and auxiliary networks and the IDC. This point is acknowledged in the CTBT and its Protocol, which make several references to the need to take national monitoring networks into account. In this regard, it is relevant to note that national seismographic networks are not operated by military organizations, but rather by civilian agencies such as the China Seismological Bureau; and, in the United States, the US Geological Survey. National networks are increasing in number and quality. They are associated with the production of detailed bulletins of regional seismicity that typically are intended to meet objectives in the study of earthquake hazard. Such bulletins, and easy access to the underlying digital seismogram data, can be very helpful in CTBT monitoring, for the study of problem events and for improving the IDC’s routine seismicity bulletins. In years to come, it is likely that

the background of earthquakes will provide a means of calibration and new methods of data acquisition and data analysis, providing useful information that will improve the work of the IMS, and assisting in the attainment of national and international monitoring goals for a CTBT.

Acknowledgments

The work underlying this chapter has been supported by several US federal agencies including the Department of Defense and the Department of Energy. I thank Alan Douglas, Scott Phillips, and Lynn Sykes for constructive criticisms of a first draft, and John Armbruster for help with Figures. This is Lamont-Doherty Earth Observatory Contribution No. 6284.

Volcano Seismology and Monitoring for Eruptions

Stephen R. McNutt

Alaska Volcano Observatory, University of Alaska, Fairbanks, Alaska, USA

1. Introduction

Volcanoes are the sources of a great variety of seismic signals that behave differently than those from events on earthquake faults. Nearly every recorded volcanic eruption has been preceded by an increase in earthquake activity beneath or near the volcano, and accompanied and followed by varying levels of seismicity. For this reason, seismology has become one of the most useful tools for eruption forecasting and monitoring. At the present time, approximately 200 of the world's volcanoes are seismically monitored, although the number and quality of stations at each varies considerably. This represents about one out of three of the 538 volcanoes that have erupted in historic times. Over the last several decades, 55 to 70 individual volcanoes have erupted each year (Simkin, 1993). Because erupting volcanoes draw attention, over half of these are seismically monitored.

This chapter reviews some of the developments in volcano seismology over the last 25 years that have led to an improved understanding of volcanoes and the volcanic processes that cause earthquakes and other seismicity. The chapter also describes patterns and relationships in volcano seismology that form the physical basis of contemporary monitoring and forecasting.

1.1 Some Famous Early Eruptions

Throughout history the relation between earthquakes and volcanoes has been close, although there has been confusion about causal relations between the two. This is because of the parallel belts of volcanoes and earthquakes found at subduction zones, where 95% of the Earth's subaerial volcanoes are located. It is common in the historic record, and recently as well, to find an increase in reports of regional earthquakes around the times of eruptions. In spite of this, the reports of the eruption of Vesuvius in AD 79 tell of numerous local earthquakes preceding the eruptive activity. People living

near Mt. Nuovo, Italy in 1538 and Mt. Usu, Japan in 1663 fled from the areas before the eruptions because of many felt earthquakes. Early observatories at Vesuvius starting in 1856, Usu in 1910, and Hawaii in 1912 recorded different types of earthquakes and began systematic study of eruption precursors. Three weeks of felt earthquakes heralded the formation of the new volcano Paricutin in Mexico in 1943. These and many other examples illustrate that volcanoes are active seismic features.

1.2 Key Developments in Volcano Seismology

Many of the key developments in volcano seismology have been driven by the different types of seismic events that volcanoes produce. For example, explosion earthquakes and volcanic tremor have required very different theories for their explanation than tectonic earthquakes. Recently, with the advent of broadband seismology, new types of events have been identified with small source sizes that produce very long-period seismic energy. Another key development during the last 25 years has been the proliferation of modern computers, which has led to dramatic improvements in speed and precision in locating earthquakes, and in determining properties of seismic waves, often in near real time. For example, many digital data acquisition systems record at 100 samples per second, so the arrival times can be measured to the nearest 0.01 sec as opposed to 0.1 sec for paper records and 0.05 sec for film recorders. This precision, together with close station spacing, has the effect of improving location accuracy, and the best-located volcanic earthquakes have formal errors as low as 50–100 m horizontally and 100–300 m vertically.

1.3 Volcano Seismology Versus Earthquake Seismology

Many methods or techniques for data analyses are first developed for tectonic earthquakes and then later applied to

volcanoes. This occurs because felt or damaging earthquakes are more common and widespread than eruptions, and consequently there are more seismologists than volcanologists and more research money is spent on earthquakes than on volcanoes. Once techniques are developed by seismologists in general, they are easily applied to volcanoes because volcanoes are small, their locations are known, and seismicity is often concentrated beneath the volcanoes. Analyses of individual seismic events at volcanoes are complicated by the active and passive involvement of fluids, e.g., magma, water, or gases. These produce analytic and computational complexity.

2. Instruments and Networks

Most seismometers used to monitor volcanoes are located on the flanks at distances within 15 km. A typical network is shown in Figure 1. About a third of the monitored volcanoes have at least one station within 1 km of the active vent. Modern networks generally consist of six or more stations. Station spacing of a few kilometers enables better detection of small earthquakes and generally small location errors (<0.5 km). Data are telemetered to a common site and recorded on drum recorders as well as on digital computers.

FIGURE 1 Map of local seismic stations near Shishaldin Volcano, Alaska. Circles are seismic stations, triangles are volcanoes, and the square is a town. All seismic stations are short-period single-component (vertical) except SSLS, which has three components. Although designed to monitor Shishaldin, the network also provides data for Isanotski and Roundtop volcanoes. Most well-monitored volcanoes have similar networks of 6–8 stations.

2.1 Short-Period and Broadband Seismometers and Telemetry

Most seismometers at volcanoes are short-period (1 sec) vertical instruments that record useful data between about 0.7 and 30 Hz. Modern three-component, digitally telemetered, high dynamic range, broadband seismometers record over a much wider band of frequencies (0.02–50 Hz). Such broadband seismometers also have a much higher dynamic range, up to 145 dB when using digital telemetry, as opposed to about 40 dB for analog telemetry. Temporary deployments of these broadband instruments have become common recently, and permanent deployments of 1 to 10 instruments at well-monitored volcanoes are becoming more widespread (e.g., Kawakatsu *et al.*, 1992; Falsaperla *et al.*, 1997; Ohminato *et al.*, 1998). Microphones are often added to seismic stations to add an additional independent data channel. They are used to record air waves from explosions (Garces and Hansen, 1998) and the radiated sound field from some volcanic tremors (Garces *et al.*, 1998). They also measure thunder from volcanic lightning and atmospheric pressure fluctuations from wind and storms.

A seismometer in the vicinity of a volcano will typically record seismic signals from four sources: (1) the volcano, (2) local earthquakes (<15 km), (3) regional earthquakes (>15 km), and (4) teleseisms (generally >600 km). Part of the job of the volcano seismologist is to discriminate these. It is helpful to record data from several stations at regional distances of 50–200 km to aid in the identification process. Two examples illustrate why these are helpful. At Nevado del Ruiz volcano, Colombia, in November 1985 and later, many earthquakes from the Bucaramanga nest, a persistent deep source of earthquakes beneath Colombia, appeared on seismograms from stations near the volcano. The Bucaramanga event seismograms resembled many of the volcanic events, and their occurrence created confusion (R. White, personal communication, 1986). At Spurr volcano, Alaska, in 1992, the seismic signal for two eruptions began gradually but the third began sharply and its onset looked like that of a regional earthquake. However, the pattern of arrival times and relative amplitudes at local versus regional stations quickly revealed that the event was an eruption.

The distance from an earthquake to a seismic station and the magnification of the station are the main factors that determine the magnitude detection threshold, the smallest signals that can be recorded. Typical magnifications at volcanoes are 5000 to 50 000, and the corresponding magnitudes of detection are about $M=0$ to $M=1$ for the 1 to 15 km distances involved. It is desirable to record the smallest earthquakes possible, but because volcanoes often have high noise levels, this is usually achieved by putting stations close to the vent rather than operating more distant stations at higher magnifications. A number of volcanoes are monitored indirectly because a nearby (>15 km) seismic station is part of a larger regional seismic network.

2.2 Volcano Monitoring in Near Real Time

To retain small volcanic events and emergent signals like tremor, several observatories continuously record digital data. These can be digitally filtered to remove noise and hence improve the signal-to-noise ratio. Automation of tasks has improved the ability to analyze many types of data in near real time, which leads to better methods of both forecasting and characterizing eruptions in progress. For example, the Real-time Seismic Amplitude Measurement (RSAM) system (Endo and Murray, 1991) and near real time spectrograms (Benoit *et al.*, 1998) measure time-domain amplitudes and frequency-domain amplitudes automatically. These systems produce plots of time series at intervals of 10 min, 1 h, 1 day, 3 days, etc., which are available for inspection on World Wide Web sites administered by the responsible agencies. Calibration information for each seismic station is stored electronically and used to help determine earthquake magnitudes and the reduced displacement (see Section 6.3) of continuous signals such as volcanic tremor. These normalized measures allow comparison between different volcanoes.

2.3 Array Processing

Some volcanic signals have gradual onsets or very long durations (hours to days or more). For these events, traditional location methods, which depend on measuring arrival times for *P* and *S* waves, cannot be used. New techniques use data from dense networks or “arrays” (e.g., Kvaerna and Ringdal, 1992). Here, the stations are very close, a few tens to hundreds of meters apart (e.g., Fig. 2), so it is possible to see the same wave coherently on all the stations (the wave need not be a first or prominent arrival). Because the physics of waves is well known, it is possible to determine what type of wave is present, which direction it is coming from, and how fast it is moving. All these provide information about the sources. Thus, dense arrays can be used like antennae to discern features, such as slowness, of specific seismic waves even when the signals are weak or noise is present (e.g., Kvaerna and Doornbos, 1986). Array methods look at different features of volcanic seismograms and thus extend the information available for analyses (e.g., Goldstein and Chouet, 1994; Oikawa *et al.*, 1994; Metaxian *et al.*, 1997; Chouet *et al.*, 1998).

2.4 Typical Observatories

Volcano observatories vary widely in location and sophistication. The simplest observatory might be a small observation hut, with a single seismograph recorded on paper on a revolving drum. Many larger observatories are located near volcanoes at distances of 10–100 km, and seismic data from local and regional stations are telemetered to them by cable, radio, and telephone. Some observatories are co-located with universities or other research organizations. These may be

FIGURE 2 Maps of two seismic arrays deployed at Kilauea Volcano, Hawaii, in 1996. (a) The A1 antenna. All seismometers are short-period three-component sensors. (b) The B line. This linear array had vertical sensors (circles) and three-component sensors (triangles).

hundreds of kilometers from the volcanoes of interest, yet the vast array of modern communications make such facilities common and economic. They are, further, safe from large eruptions that may affect closer facilities. There are over 73 members of the World Organization of Volcano Observatories (WOVO, 1997) covering more than 119 volcanoes, most with some kind of seismic monitoring capability (see Appendix on the attached Handbook CD, under directory \25McNutt).

3. Terminology and Types of Events

Active volcanoes are the sources of a great variety of seismic signals. Traditionally, volcanic earthquakes have been classified based on seismogram appearance into four different types: high-frequency or A-type, low-frequency or B-type, explosion quakes, and volcanic tremor (Minakami, 1974). This classification scheme works very well at a large number of volcanoes, but see below for additional discussion. Other local signals, such as those caused by glaciers or landslides, are also recorded

FIGURE 3 Typical waveforms of volcanic earthquakes. (a) High-frequency or volcano-tectonic earthquake, 6.8 km depth, Redoubt Volcano, Alaska, station RED, 8 km from the vent. (b) Hybrid or mixed-frequency event, -0.6 km depth (0.6 km above sea level), Redoubt Volcano, station RED. (c) Low-frequency or long-period event, -0.4 km depth, Redoubt Volcano, station RED. (d) Volcanic tremor, Redoubt Volcano, station RED. (e) Explosion quake, Pavlof Volcano, Alaska, station PVV, 8.5 km from the vent (note prominent air-wave arrival marked by arrow). (f) Low-frequency or B-type event, Pavlof Volcano, station PVV. (g) Volcanic tremor before eruption, Mt. Spurr, Alaska, station CRP, 4.8 km from the vent. (h) Volcanic tremor during eruption, Mt. Spurr, station CRP. Amplitudes are normalized.

at volcanoes. Although Minakami's original classification included restricted depth ranges for various events, these have often been relaxed because of improvements in location accuracy and better understanding of source and propagation effects. Examples of volcanic events from several volcanoes are shown in Figures 3, 4, and 5. In the following sections, the events are described and source processes are briefly discussed.

3.1 High-Frequency Events

Most high-frequency (HF) events are thought to be caused by shear failure or slip on faults, and differ from their tectonic counterparts only in their patterns of occurrence. At volcanoes, earthquakes typically occur in swarms rather than mainshock-aftershock sequences. A swarm may be defined as a group of many earthquakes of about the same size and location with no dominant shock. In practical terms, the difference in magnitude between the largest and second largest event of a swarm is 0.5 magnitude units or less, as opposed to 1.0 unit or more for mainshock-aftershock sequences. HF events have clear *P* and *S* waves, and dominant frequencies are 5–15 Hz. Higher frequencies may be generated at the source, but are not recorded because of instrumental limitations or high local attenuation. A typical small HF event is shown in Figure 3a.

Some events with the typical frequencies of HF events show clear evidence of non-double-couple focal mechanisms (Julian *et al.*, 1997) or simultaneous shear and tensile faulting (Shimizu *et al.*, 1987), and hence imply fluid involvement. Thus frequency content alone does not uniquely indicate the process. Some studies of HF events have focused chiefly on attributes of swarms (e.g., Okada, 1983; Benoit and McNutt, 1996) as opposed to individual events.

3.2 Low-Frequency Events

Low-frequency (LF) or long-period (LP) events are at the heart of volcano seismology, are an area of active research, and are likely related to fluid flow. Most low-frequency events are thought to be caused by fluid pressurization processes such as bubble formation and collapse, but also by shear failure, tensile failure, or nonlinear flow processes that occur at very shallow depths for which attenuation and path effects play an important role. These events often have emergent *P* waves, lack *S* waves, and have dominant frequencies between 1 and 5 Hz, with 2–3 Hz most common. Examples of low-frequency events are shown in Figures 3c, 3f, 4a, and 4b.

Prior to eruption, magma must move from depth to the Earth's surface through conduits, dikes, sills, reservoirs, or combinations of these. Thus, models of LF volcanic earthquakes select a conduit geometry, such as a rectangular crack, a cylindrical pipe, or a fluid sphere, then attempt to reproduce seismograms by appropriate choice of length, width, and thickness, and the velocity and other properties of the material within it, which can be either magma or water (e.g., Chouet,

FIGURE 4 Tornillo, also called long-coda event or long-period event. (a) Redoubt Volcano, station REF, 3 km E of the vent. (b) Same event as (a) as recorded at station RSO, 3 km S of the vent (1 April 1992). Amplitudes are normalized.

1992, 1996; Iguchi, 1994; Fujita *et al.*, 1995; Nakano *et al.*, 1998). Seismicity similar to that at volcanoes is found at geysers and geothermal areas (Kedar *et al.*, 1996). A source of mechanical energy is needed; this can be a small earthquake adjacent to a conduit, a flow transient or pressure fluctuation within a conduit, gas bubbles expanding or contracting, a shock wave from choked flow, or other causes. Some workers consider the source to be the mechanical energy alone, while others treat the source as the ensemble of the mechanical energy and the resonant response of the fluid in conduits or dikes (Garces and McNutt, 1997). Low-frequency events are thought to be closely related to volcanic tremor.

Some earthquakes share attributes of both high and low-frequency events. These are called hybrid events (e.g., Power *et al.*, 1994). For example, the event shown in Figure 3b displays the high-frequency onset of an HF event, but the coda is similar to those of LF events. It is thought that such events represent a mixture of processes, such as an earthquake occurring adjacent to a fluid-filled cavity and setting it into oscillation (Chouet, 1992). Others suggest that hybrids are shallower than LF events and thus preserve most of their high-frequency energy, which is attenuated for deeper events (Neuberg *et al.*, 1998).

3.3 Explosion Earthquakes

Explosion quakes accompany explosive eruptions, and many are characterized by the presence of an air-shock phase on the seismograms. There is a partitioning of energy at the source: Part of the energy travels through the ground as seismic waves and part travels through the air as acoustic or air waves (Garces and Hansen, 1998). The air wave then couples back into the ground and is detected by the seismometer.

The air wave also shows up clearly on microphones or barographs (Ishihara, 1985). An example of an explosion earthquake is shown in Figure 3e. Source parameters of explosion earthquakes have been studied by Nishimura (1995), who found that the peak amplitude of the modeled single force scaled with the source duration.

3.4 Volcanic Tremor

Volcanic tremor is a continuous signal of duration minutes to days or longer. The dominant frequencies of tremor are 1–5 Hz (2–3 Hz is most common), similar to LF events, and many investigators have concluded that tremor is a series of LF events occurring at intervals of a few seconds. Harmonic tremor and spasmodic tremor are two special cases of more general volcanic tremor. Harmonic tremor is a low-frequency, often single-frequency sine wave with smoothly varying amplitude; or sometimes it consists of a fundamental frequency with many overtones. Spasmodic tremor is a higher-frequency, pulsating, irregular signal. Intermittent or “banded” tremor occurs in regular, periodic bursts separated by periods of quiescence of uniform duration. The resulting pattern looks like stripes or bands on seismograms recorded on rotating drum recorders (Fig. 5). Examples of volcanic tremor are shown in Figures 3d, 3g, 3h, and 5.

Models for tremor are analogous to those for LF events (Section 3.2), and the two are often treated together. While most workers attempt to model the source (e.g., Julian, 1994; Nishimura *et al.*, 1995; Chouet, 1996; Ida, 1996; Neuberg *et al.*, 1998), other workers have elucidated propagation effects of the wave fields (Gordeev, 1992; Ereditato and Luongo, 1994; Kedar *et al.*, 1996; Metaxian *et al.*, 1997) and the relationship to eruptions (Gresta *et al.*, 1991; McNutt, 1994).

The number of earthquakes versus magnitude obeys a power law, known in seismology as the Gutenberg–Richter frequency–magnitude relation. There are more small earthquakes than large ones, and the relative numbers of events form a power-law distribution. Volcanic tremor, however, obeys an exponential law, based on analyses of data from eight volcanoes (Kilauea, Spurr, Pavlof, Redoubt, Karkar, Ulawun, Fuego, and Arenal) and one geothermal area (Old Faithful; Fig. 6) (Benoit, 1998). For tremor, which is a continuous signal, we cannot count the number of events, so we compute the duration at different amplitudes. Synthetic experiments by Benoit (1998) have shown that this is equivalent to counting events. The evidence to date favors a fixed source size at each volcano affected by variable pressure fluctuations; however, the full implications of the exponential law for the source of volcanic tremor are not yet well established.

3.5 Very Long-Period Events

Over the past decade, new broadband seismometers have been deployed at volcanoes. These have the ability to detect

FIGURE 5 Banded tremor from Manam Volcano, Papua New Guinea, station TBL, 4 km from the vent (30 March 1992). Bands correspond to strong phases of subcontinuous Strombolian activity. Tick marks are at 1-min intervals, recording speed is six lines (revolutions) per hour.

FIGURE 6 Volcanic tremor data from Mount Spurr, Alaska, comparing an exponential (a) and a power law (b) model. Note that the vertical axis is logarithmic in both cases, but the horizontal axis is linear for the exponential model and logarithmic for the power law model. The circles show the duration of tremor observed at various amplitudes; strong tremor occurs less often than weaker tremor. The lines are weighted least-squares mathematical fits of the data to the two models shown. The data fit better using the exponential model, as shown by the higher value of the correlation coefficient R^2 . (Modified from Benoit, 1998.)

a wider frequency band, particularly at the low end (down to $f=0.016$ Hz, or a period of 60 sec). Not surprisingly, a new class of events called very long-period (VLP) events have been observed at some volcanoes. Observations to date show events with periods of 3–20 sec originating from shallow depths of 1.5 km or less under active volcanoes including Kilauea (Ohminato *et al.*, 1998), Stromboli (Neuberg *et al.*, 1994; Chouet *et al.*, 1998), Aso (Kawakatsu *et al.*, 1994;

Kaneshina *et al.*, 1996), Sakurajima (Kawakatsu *et al.*, 1992; Uhira and Takeo, 1994), Mount Erebus (Rowe *et al.*, 1998), Satsuma-Iwojima (Ohminato and Ereditato, 1997), and pyroclastic flows at Unzen (Uhira *et al.*, 1994). The VLP events at these volcanoes have been associated with either eruptions or vigorous fumarolic activity, and the events have fairly small amplitudes. An example of a VLP event is shown in Figure 7.

FIGURE 7 Data from a broadband three-component network operating at Kilauea in February 1997. (a) Record section of the vertical component of velocity in band 10–100 s at seven stations (amplitudes normalized in order to emphasize waveform similarities among the stations). (b) Broadband seismic network. Circles are seismic stations, and unbroken lines represent pit craters, faults, and the ring fracture system. Broken lines around shaded region represent 90%, 93%, and 96% semblance. (c) Comparison between observed waveforms (bold lines) and synthetics (thin lines) obtained from inversion of these waveforms (examples depict fits obtained at three stations). (d) Model of source mechanism derived from inversion of network data. This is a rectangular near-vertical dyke, which undergoes a volume change of 700 m^3 associated with the dominant pulse shown in part (a). (Courtesy B. Chouet.)

Normally it takes a large structure, such as a long fault, to produce waves with these long periods. However, many of the VLP events at volcanoes appear to come from small source zones despite the long wavelengths. Some current models suggest that these events may be produced as magma moves through a flapper valve (such as a restriction in a dike or sill) in distinct pulses (e.g., Ohminato *et al.*, 1998). Additionally, theoretical calculations show that it is possible for a crack or tube filled with fluid to produce long-wavelength

(and long-period) waves if the acoustic velocity in the fluid is slow compared to that of the rigid walls. The interaction between the fluid and walls produces low phase velocities along the interface (e.g., Ferrazzini and Aki, 1987; Uhira and Takeo, 1994). Such waves are called crack waves or tube waves.

During its climactic eruption on 15 June 1991, Mount Pinatubo, Philippines, produced strong seismic waves with periods of 228–270 sec (Kanamori and Mori, 1992). These are

thought to be caused by a type of oscillation in the atmosphere in which thermal energy from the vent travels up and then reflects off the top of the ash column (in this case in the stratosphere). These waves also coupled into the ground and appeared on stations thousands of kilometers away for over 2 h.

Broadband sensors have been deployed at a number of volcanoes that produced no VLP signals, even though several of these were erupting. They include Mount Spurr, Akutan, and Augustine in Alaska (McNutt *et al.*, 1997), Montserrat (Neuberg *et al.*, 1998), and Arenal (Benoit and McNutt, 1997; Hegarty *et al.*, 1997) volcanoes. Further, the scientific community has yet to record any precursors to truly large eruptions on broadband instruments. In spite of this, the VLP signals made visible by the new broadband instruments are an exciting part of volcano seismology, and it is anticipated that many new advances will be made in this area over the next few years.

3.6 Surficial Events

Seismometers located on volcanoes record a variety of local signals caused by shallow processes. These include non-volcanic processes such as glacial events, shore ice movement, and landslides, as well as volcanic processes such as outburst floods and lahars, pyroclastic flows, and rockfalls from crumbling lava domes. Some of the seismograms are similar, so they must be recognized and properly treated by analysts.

3.6.1 Glacial Events

Volcanoes at high latitude and tall volcanoes host glaciers, which produce seismic events along the ice–rock boundary and within the ice when cracks form. Because the seismic wave velocity in ice is lower than that in rock, the seismic waves may become partially trapped in the ice and set up oscillations of the ice itself. Seismograms from such events resemble those for LF volcanic events. Glacial events are more common in the summer months when the glaciers are moving faster.

3.6.2 Shore Ice

Ice forms from sea water when the air temperature falls below -12°C . Large blocks of such ice gather on the shores of Augustine Island, Alaska, and move as the tides ebb and flood. When the blocks collide or break, they produce seismic events because the blocks are coupled to the ground. The events are surficial, so the seismic waves are mostly low-frequency surface waves traveling in thin sediment layers. The individual ice events resemble LF volcanic events, and the events occur in swarms of a few hours' duration because of the tides. Both of these features are similar to seismicity preceding eruptions, so one needs to measure air temperature in such situations!

3.6.3 Landslides

Avalanches and landslides of various sizes occur on volcanoes. Those associated with partial melting of ice and snow mainly occur in the spring and summer. The main avalanche or landslide generates a seismic signal of several minutes' duration, depending on the size and runout. The amplitude varies with the amount of material, with larger avalanches generating stronger seismic signals. Some landslides on volcanoes (and elsewhere) are preceded by small discrete seismic events whose rate of occurrence increases up to the time of the main event. This is similar to a common pattern of earthquakes before eruptions so, again, additional information is needed to distinguish between volcanic and nonvolcanic causes of the seismograms.

3.6.4 Rockfalls

Rockfalls are a special type of landslide in which one or a few pieces of bedrock become detached and free fall. They are especially common at volcanic domes and at volcanoes with very steep slopes or cliffs. In the summer of 1995 workers at Mount Spurr, Alaska, observed rocks more than 1 m in diameter falling several hundred meters and impacting on the crater floor. The corresponding seismograms showed strong irregular local signals lasting more than one minute.

3.6.5 Pyroclastic Flows

Pyroclastic flows are products of explosive eruptions and consist of particles of hot molten rock and gases which move rapidly over the ground surface. Large-scale collapses of volcanic domes can also produce pyroclastic flows. These latter events were characterized by complex seismograms that have been modeled as a sequence of forces (Uhira *et al.*, 1994). First, rock is removed from the dome (the dome moves up slightly in response); second, the falling rock collides with the slope below (an impact); and third, the rock breaks apart and the fragments continue to move down the slope as an irregular flow. These seismograms last several minutes and may contain high frequencies, and the larger flows are associated with larger-amplitude signals.

Pyroclastic flows have also been associated with another seismic feature. At Pinatubo volcano, Philippines, pyroclastic flows traveled down a valley between two seismic stations, one of which transmitted its signal to the other. As the ash clouds rose into the air the telemetry path was interrupted for several tens of minutes, after which the signal returned. Thus, the temporary absence of the telemetry could be used to infer that pyroclastic flows were occurring.

3.6.6 Outburst Floods and Lahars

The surface melting of ice and snow, or heavy rains, may cause floods and lahars (volcanic mudflows). Similarly, a volcanic eruption under a glacier will melt the ice, and the flooding

that subsequently occurs is called a jokullhaup. All these floods or lahars cause long-duration seismic signals that resemble volcanic tremor, except that the signal is stronger near the flow channel, as opposed to tremor, which is stronger nearest the volcanic vent. The flood water travels downstream, so the source is moving. Also, the recorded frequencies may be high if the seismometer is near the flow channel, even though this may be far from the vent.

Different groups of investigators and various observatories have used a number of different *local* terminologies. This is similar to the local names of sandwiches, which can be "hoagie," "grinder," or "submarine sandwich" in different parts of the United States. However, no consensus has yet emerged about an appropriate *global* terminology. The lack of a global terminology makes it difficult to evaluate critically the observations from different volcanoes, and creates confusion in the literature. Table 1 compares several common local terminologies. Further, it is often difficult to distinguish between different types of events at a single volcano because the events may grade into one another. In such cases quantitative criteria are applied, such as *P/S* amplitude ratios, coda durations, specific frequencies, etc. Recently, Falsaperla *et al.* (1996) applied multilayered neural networks to attempt an automatic classification of seismic events at Stromboli volcano.

Different mechanisms acting at the seismic source are responsible for many of the features of the different events, and path and site effects, which are extreme at many volcanoes, may greatly modify the signals. Three principal seismic sources are (Ferrucci, 1995): shear failure, also called "double-couple" mechanisms; tensile failure, or "non-double-couple" mechanisms; and passive and active fluid involvement in producing low-frequency events and volcanic tremor. Nonlinear flow has also been modeled as a source for volcanic tremor (Julian, 1994). Differences were seen between volcanic and tectonic earthquakes by comparing magnitude using different waves (Okada, 1983), and seismic moment versus fault length (Gorelchik *et al.*, 1990). Such comparisons reveal that many volcanic earthquakes are enriched in low frequencies and occur on smaller faults than tectonic earthquakes of the same magnitude.

4. General Features and Processes Associated with Volcanic Earthquakes and Tremor

The goals of volcano seismology include monitoring the present status of a volcano, forecasting eruptions, estimating the size of eruptions in progress, locating magma chambers, and understanding the physical processes that are occurring. The following topics elucidate some of the features that are common to earthquakes at volcanoes.

4.1 Seismicity Rates, Locations, and Processes

Volcanoes nearly always have a high background level of seismicity, caused by heat; movement of groundwater, volatiles, or magma; glaciers (if present), landslides, and rockfalls; and reactions to stresses from regional tectonics, tides, or other forcing functions. Thus, a baseline of measurements of a few years is necessary to characterize the background seismicity. The background may consist of several different types of events, which are related to different processes. Typical background rates of seismicity are a few to a few tens of events per day, depending on the locations and magnifications of the seismic stations. In contrast, the rates of seismicity before and during eruptions are several tens to several hundreds or more events per day, and include larger-magnitude events. Examples of rates and magnitudes of seismicity prior to selected eruptions are shown in Table 2.

Many successful eruption forecasts have been made because of an increase in seismicity above previously recorded background levels. This is based on the idea that the level of seismicity reflects the level of volcanic activity, so the likelihood of eruption increases when earthquake swarms occur. The main physical processes monitored, however, are those associated with magma intrusion. Thus, there will always be a false alarm rate because some intrusions remain at depth whereas others reach the surface and erupt.

In general, large eruptions are relatively easier to detect than smaller ones. The volume of magma is large, and

^bLP, long-period earthquake.

earthquakes tend to be numerous as well as distributed over a large volume. Other precursors such as deformation and steaming are usually observed in conjunction with earthquake swarms. Recent examples include Mount St. Helens, Washington, 1980 (Endo *et al.*, 1981; Malone *et al.*, 1981); Pinatubo, Philippines, 1991 (Newhall and Punongbayan, 1996; Pinatubo Volcano Observatory Team, 1991); and Spurr, Alaska, 1992 (Keith, 1995). Small eruptions and many phreatic (water-driven) eruptions, in contrast, involve much smaller amounts of magma, and have subtle precursors or sometimes no precursors. They are, hence, generally harder to forecast. Recent examples include Galeras, Colombia, January–June 1993 (Munoz *et al.*, 1993); Arenal, Costa Rica,

August 1993 (BGVN, 1993); and White Island, New Zealand, February 1992 (BGVN, 1992).

Occasionally “unexpected” eruptions occur; often these take place during the later phases in a sequence of eruptions. Even though these may be large, they may have subtle or undetectable seismic precursors. This is a consequence of the vent remaining “open” or mechanically weak following an initial stage of activity, preventing buildup of stresses that would cause earthquakes. A recent example is the second eruption of Mount Spurr in August 1992, which occurred without immediate detectable precursors (Power *et al.*, 1995). The eruption lasted 3.5 h, produced $52 \times 10^6 \text{ m}^3$ of tephra, and ejected its ash cloud into the stratosphere.

Generally, volcanic earthquakes occur beneath the point of eruption. This helps reduce the monitoring problem to that of estimating the time of eruption, since the place is considered known. However, several cases have occurred in which the locations of earthquake swarms did not coincide with the eruptive vent, because different mechanisms were acting (Nakamura, 1984). During the Matsushiro, Japan, earthquake swarm of 1965–1967, which began beneath Mt. Minakami, an extinct volcano, epicenters were aligned NE–SW, but a fissure oriented NW–SE appeared at the ground surface. Water flowed from this fissure but no magmatic eruption occurred. During the Miyake-jima, Japan, basaltic eruption of 1962, the epicenters were located NW of the summit crater but the eruption occurred from a flank fissure on the NE side. More recently, the initial earthquake swarms prior to the dacitic eruption of Pinatubo occurred about 5 km NW of the volcano. Twelve days before the climactic eruption, these earthquakes declined and vigorous shallower swarms began beneath the eventual eruption site (Wolfe, 1992; Harlow *et al.*, 1996). For volcanic systems with large dimensions, earthquakes may be widely separated: for Katmai, Alaska, 1912 there was a 10 km separation between the collapse structure (Mt. Katmai) and the Novarupta vent (Eichelberger *et al.*, 1991); at Rabaul, Papua New Guinea, 1994, two vents, Tavurvur and Vulcan, erupted simultaneously 10 km apart (BGVN, 1994), while precursory earthquakes were distributed in an annulus surrounding the caldera. These cases demonstrate that earthquakes occur where stresses are concentrated, not necessarily where the magma is located.

It is expected that earthquake locations will migrate from depth toward the Earth's surface as magma rises from depths prior to eruption. There are, however, few well-documented cases of such a trend. This overall pattern was first shown for Kilauea volcano, Hawaii, in 1959 (Eaton and Murata, 1960); more recent examples include Augustine, Alaska, 1986 (Power, 1988); Unzen, Japan, 1991 (Ohta *et al.*, 1992); Pinatubo, 1991 (Harlow *et al.*, 1996), and additional 1960–1983 eruptions of Kilauea (Klein *et al.*, 1987). One spectacular case of lateral migration of hypocenters was observed at Krafla in September 1977 (Brandsdottir and Einarsson, 1979); when the earthquakes passed a geothermal borehole, fresh pumice erupted from the hole!

Differences between seismic activity at basaltic versus andesitic and dacitic volcanoes may be subtle. Extremely short-duration swarms of small events are more common at basaltic volcanoes. For example, the January 1991 eruption of Hekla volcano, Iceland, occurred after an earthquake swarm lasting only 0.5 h, with the largest event about $M = 3$ (Gudmundsson *et al.*, 1992; Linde *et al.*, 1993). Most of the handful of known eruptions that occurred without detectable precursors took place at basaltic volcanoes (e.g., Hekla, 1981, Gronvold *et al.*, 1983; Mt. Etna, Italy, flank, March, 1985, McClelland *et al.*, 1989, p.71). Energetic earthquake swarms after eruptions are common at basaltic centers. Spatially,

basaltic centers more often produce flank eruptions, whereas andesitic and dacitic volcanoes tend to erupt repeatedly from the same central vent.

4.2 b Values at Volcanoes

In general, there are many more small earthquakes than large ones. This is a consequence of the fact that the size distribution of earthquakes obeys a power law, which in seismology is of the form $\log_{10} N = a - bM$ (where N is cumulative number of events, M is magnitude, and a and b are constants) and is known as the Gutenberg–Richter relation. The slope, or b value, determines the relative number of large versus small events. While for tectonic earthquakes the b value has typical values of 0.8–0.9 worldwide, more extreme values have been observed at volcanoes. High-frequency events have b values ranging generally between 0.6 and 1.3, but low-frequency events have b values of up to 3.0 (Fig. 8). This means, for low-frequency events, that small earthquakes dominate, and also implies that the source size is restricted (Wyss, 1973). Laboratory experiments have shown that b value increases with heat (Warren and Latham, 1972) and pore pressure (Wyss, 1973), decreases with applied stress (Scholz, 1968), and

FIGURE 8 Frequency–magnitude relations for high-frequency (A) and low-frequency (B) earthquakes at Mount St. Helens during the March to May 1980 swarm. Regression lines fit to selected portions of the data produce the b values indicated. (From Endo *et al.*, 1981.)

FIGURE 9 Tomography of Mono Craters, California, using P waves from distant earthquakes. (a) Map of tectonic and geographic features of the area of Mono Craters, just northeast of Long Valley caldera. Shaded areas are Holocene volcanic flows and domes. (b) An E–W cross section showing tomographic results. The velocities vary from 3.5% higher to 7% lower than the reference values. The strongest anomaly, a 7% lowering of the velocity (black rectangle) occurs 9–16 km beneath the Mono Craters. (From Iyer, 1992.)

increases when material heterogeneity increases (Mogi, 1962). Determination of the b value for volcanic earthquakes is thus an important diagnostic tool for identifying changes in seismicity that may indicate changing processes.

4.3 Some Seismic Features of Magma Chambers

Magma is thought to be stored in chambers or reservoirs underground, and seismology is useful to determine the parameters of such chambers. Magma chambers at stratovolcanoes

are generally equant in shape, and on the order of $1\text{--}20\text{ km}^3$ in volume. Those at calderas are larger. Their depths are mapped at about 5–20 km or deeper based on several techniques. First, seismic tomography, similar to medical tomography, requires seismic waves to travel through the target region. Thus, a good distribution of earthquakes and seismic stations is needed; both local and distant earthquakes have been used as sources for such studies. The technique exploits the fact that P waves speed up in competent rock and slow down in unconsolidated materials or magma. An example of a tomographic image of a magma chamber under Mono Craters, California, is shown as Figure 9; see Chapter 26 by Benz *et al.* for additional examples. Second, S wave screening exploits the fact that S waves cannot pass through liquids. Thus, the target region will be illuminated by the presence of P waves but lack of S waves for those waves that pass through magma. Third, post-eruption seismicity is often concentrated at depths of 5–20 km. Here, the removal of magma upward during eruption causes stress changes at depth that induce earthquakes. The idea is that the magma chamber walls collapse inward, and earthquakes are concentrated where these processes are most pronounced.

A new technique that requires well-distributed seismicity (as opposed to concentrated at one spot) looks for systematic spatial variation in the b value, discussed earlier. A 2D or 3D grid is made, then the b value is determined for the 100 earthquakes nearest to each grid point (Wiemer *et al.*, 1998). The results are displayed in maps or cross sections (see Color Plate 6). It has been shown in the laboratory that heat, high pore pressure, low applied stresses, or heterogeneous materials all produce high b values. These are also the conditions that would be expected in the vicinity of magma bodies. Although this technique cannot uniquely identify which process is dominant, strong anomalies have been found at depths of 3–4 km and 7–9 km beneath six volcanoes studied. Examples of b value anomalies thought to represent magma chambers beneath Mount St. Helens and Mount Spurr are shown in the Plate.

5. Case Histories

We consider the earthquake activity at six volcanoes to illustrate the variety of seismic activity. The six include small and large eruptions, a noneruption, and systems dominated by basalt, andesite, and dacite magmas. The volcanoes chosen had high-quality seismic data. Parameters of the four cases are summarized in Table 3. The bibliography gives at least one recent reference for each.

5.1 Mount St. Helens, May 1980: A Large Dacite Eruption

Mount St. Helens, Washington, USA, produced a large explosive dacite eruption including a lateral blast on 18 May 1980, following 59 days of increased seismicity (Endo *et al.*, 1981;

TABLE 3 Parameters of Volcanic Activity: Seismic Case Histories

Units are cm².^dNA = not applicable.**FIGURE 10** Counts of Mount St. Helens earthquakes larger than $M = 2.5$ per 6 h, volcanic tremor (vertical lines, length proportional to tremor duration), and square root of cumulative energy release (a way to convert from magnitude to energy) from 20 March to 24 May 1980. (After Endo *et al.*, 1981, Malone *et al.*, 1981.)

Malone *et al.*, 1981). On 20 March 1980 an $M = 4$ earthquake occurred, followed by many smaller events. Activity increased, reaching eight $M > 4$ events in a single hour on 25 March. Phreatic eruptions began on 27 March. The earthquake sequence eventually included over 10 000 earthquakes, including HF and LF events and volcanic tremor (Fig. 10). Most events were located at depths of 3–7 km beneath the north flank of the volcano, the site of the eventual eruption (Fig. 11). There were no immediate precursors in the hours before the climactic eruption. An $M = 5.1$ earthquake coincident with

a landslide initiated the eruption by causing a sector collapse that uncapped the volcano (Kanamori *et al.*, 1984). This is another example of a co-eruptive process, in this case a landslide, that produces seismic signals. Strong volcanic tremor accompanied the main eruption (Table 3). Deep (5–20 km) earthquakes began shortly after the eruption and lasted for several days (Weaver *et al.*, 1981). Later smaller eruptions were generally preceded by swarms of small earthquakes lasting several hours to several days, and were accompanied by volcanic tremor (Malone *et al.*, 1981; Swanson *et al.*, 1983).

FIGURE 11 Epicenter map and cross section of seismicity from 27 March to 18 May 1980, at Mount St. Helens volcano. Contour on map is 1219 m (4000 ft); datum for cross section is average elevation of seismic stations, approximately 914 m (3000 ft). (Modified from Endo *et al.*, 1981.)

5.2 Mount Spurr, June–September 1992: A Typical Andesite Eruption

The Crater Peak vent of Mount Spurr, Alaska, erupted on 27 June 1992 following a 10-month swarm of HF events (Fig. 12; Alaska Volcano Observatory, 1993). The largest event of this swarm was $M=1.8$. Bursts of volcanic tremor began three weeks before the first eruption, and continuous tremor began 19 h before (Fig. 12). The final precursor to the first eruption was a 4 h swarm of shallow HF events directly beneath the active vent (Power *et al.*, 1995). The Vulcanian eruption lasted 4 h and produced $44 \times 10^6 \text{ m}^3$ of andesite tephra (Keith, 1995). The second, larger eruption on 18 August occurred essentially without precursors. The third eruption, on 17 September, occurred following several weeks of increased deeper (15–40 km) seismicity and 3 h of small shallow events and weak tremor. This last eruption was followed by a vigorous swarm of

FIGURE 12 Seismicity in 1991 and 1992 associated with the eruptions of Mt. Spurr. (a) Number of events per week. Episodes of volcanic tremor are shown as horizontal bars. (b) Earthquake depth versus time. The three eruptions are shown as arrows. (c) Volcanic tremor cumulative duration versus time for June 1992. Data are computed for 6 h intervals. The eruption occurred on 27 June (arrow). (From Power *et al.*, 1995, McNutt *et al.*, 1995.)

earthquakes between 5 and 10 km depth (Fig. 12). A shallow swarm of several hundred events occurred on 9 and 10 November without eruption.

5.3 Arenal Volcano, July 1968 and Continuing: Strombolian Activity

Arenal Volcano, Costa Rica, erupted explosively in July 1968 (Minakami *et al.*, 1969) after several days of felt earthquakes (no local seismometers were operating at the time). Four new vents were formed along a fissure. At first activity was strongest at the lower craters, but afterwards activity shifted to

a vent near the summit and near steady-state eruption of andesite has occurred ever since (Melson, 1989; BGVN, 1999). The eruption of a block andesite lava flow is punctuated several times per hour by small explosive eruptions of several types. A typical sequence in spring 1994 was an explosion, followed by a “whoosh” that sounded like a jet plane, followed by “chugs” that sounded like a steam locomotive (Benoit and McNutt, 1997). The seismic expression of these is an explosion quake, followed by irregular tremor, then regular tremor with variable amplitude (see Color Plate 6), which gradually fades to background levels (similar data and frequencies are found in acoustic data; Garces *et al.*, 1998). The tremor consists of several integer harmonics or overtones, and these change frequency systematically over the course of several minutes (Color Plate 6). This suggests that the upper few hundred meters of magma in the conduit is changing its pressure or bubble concentration, hence its velocity and frequency (Benoit and McNutt, 1997). Every few years, activity escalates and larger explosions occur, producing pyroclastic flows.

5.4 Long Valley, May 1980 and Continuing: A Restless Caldera

The Long Valley caldera region of eastern California has been a prolific producer of earthquakes from 1980 to 2000. The sequence began on 25 May 1980 when three $M=6$ earthquakes occurred, along with thousands of smaller events, followed two days later by a fourth $M=6$ event (Fig. 13; Hill *et al.*, 1985). Several of the events had significant non-double-couple components, suggesting possible fluid injection (Julian and Sipkin, 1985), rupture complexity (Wallace, 1985), or effects from near-source structural inhomogeneities (Wallace, 1985). The relative contribution of these effects remains controversial. Extensive ground deformation had also occurred, with uplift of 0.5 m near the center of the caldera. Later, it was found that measurable deformation actually preceded increases in earthquake activity by about two months, suggesting that earthquakes were a symptom of the deformation (or whatever caused it, such as underground movement of magma) rather than the cause (Langbein *et al.*, 1993). Repeated swarms of earthquakes occurred in the

FIGURE 13 Map of Long Valley caldera and Sierra Nevada mountains to the south showing epicenters of $M > 1.2$ earthquakes occurring from January 1978 to June 1995. Each symbol represents one earthquake, and symbol size is proportional to magnitude. The large white circles are the four $M \sim 6$ earthquakes that occurred in May 1980. ML is the town of Mammoth Lakes; WC is the epicenter of the $M=5.4$ Wheeler Crest earthquake of October 1978; Hy 395 is Highway 395; L. Crowley is Lake Crowley. The caldera outline is shown as a solid line and the uplifted resurgent dome by a dashed line. (From Hill, 1996.)

southern part of the caldera, and the strongest of these, in January 1983, included two $M=5.3$ events. Altogether 27 earthquakes with $M > 5$ have occurred in and near the caldera over the last 20 years, a very high rate. No eruption has occurred; however, large quantities of CO_2 gas have been measured near Mammoth Mountain and have caused tree kills (Hill, 1996). It is also thought that several of the earthquake swarms accompanied intrusions of magma to shallow depths of about 5 km. Long Valley has become an archetype of a “restless caldera.”

5.5 Kilauea, January 1983: A Fissure Eruption

Kilauea Volcano, Hawaii, is a shield volcano with a summit caldera and rift zones to the southwest and east. Earthquakes are numerous and are associated with all three of these features, as well as with a deeper nearly horizontal fault on the south flank of the volcano (Fig. 14). New magma typically rises from depth near the summit, causing earthquake swarms and inflation, then either erupts near the summit or moves laterally into the east rift zone, accompanied by summit deflation. A fissure eruption began on the east rift zone on 3 January 1983, near Napau Crater, extending 8 km downrift toward Puu Kamoamo (Wolfe, 1988). Prior to this, earthquake swarms had occurred on 26 September and 9 December 1982, near the summit, followed by an intense swarm on the upper east rift from 30 December 1982 to 6 January 1983 (Fig. 15). Most of the Earthquakes were shallow, between depths of 2 and 4 km, and the largest was $M = 4.2$ (Koyanagi *et al.*, 1988). Volcanic tremor first occurred weakly, then was strong at frequencies of 5–10 Hz at the time of fissure opening. Later, tremor was predominantly 2.5 Hz with bursts of stronger activity paralleling the behavior of intermittent high lava fountains. After the initial fissure eruptions, the volcanic activity localized south of Puu Kamoamo (Fig. 14) and formed a new cone called Puu Oo. In July 1986, activity shifted to a lava lake 3 km downrift. The eruption is continuing as of this writing, and is Kilauea’s longest historical eruption. Because of its high activity, Kilauea has been the site of numerous detailed investigations including the deployment of the arrays shown in Figures 2 and 7b.

5.6 Pavlof, September–December, 1996: A Long-Duration Strombolian Eruption Punctuated by Explosive Phases

Pavlof is the most active volcano in North America and has had over 40 eruptions since 1760 (Miller *et al.*, 1998). It is monitored by a network of six seismic stations within 11 km, and three others from 33 to 40 km. An eruption report was received on the morning of 16 September 1996, from residents of Cold Bay, 37 miles to the SW. This was a surprise to scientists because no significant precursors had been seen on seismic records, which were partially obscured by a storm in

the area. Later analyses showed that the small-scale seismicity had actually increased on 11 September, which was only revealed after digitally filtering the data (Fig. 16) to remove storm noise. The eruption lasted continuously from 16 September to 4 December, declined, then had two stronger bursts on 10–12 December and 26–29 December (Fig. 17) (McNutt, 1999). The challenge during this eruption was not to forecast the onset, which was missed, but to quickly determine escalations of activity that represented more explosive phases of the eruption. These occurred five times (Fig. 17). The data were analyzed automatically in near real time (a few minutes) to determine reduced displacements (defined in Section 6.3) and these were used to establish an alarm threshold of 6 cm^2 . Further, spectrograms were computed automatically in near real time and were used to help identify explosions (with wideband air waves) and escalations in tremor, a strong but narrowband 1–3 Hz signal (Benoit *et al.*, 1998).

6. Forecasting Eruptions and Characterizing Eruptions in Progress

6.1 Generic Volcanic Earthquake Swarm Model

Common observations suggest a general model of earthquake activity at volcanoes (McNutt, 1996). The model, which is termed a generic volcanic earthquake swarm model, is shown as a time-series in Fig. 18. Seismicity rates, types of events, and dominant processes are indicated in the commonly observed temporal sequence. Variations in the involvement of groundwater, as well as variations of parameters such as magma composition, temperature, rate of flow, and volatiles content, can explain many of the observed differences from this model of seismic activity at different volcanoes. A nice example of the sequence is seen accompanying the 1989 Ito-Oki eruption (Ukawa, 1993; Ukawa and Tsukahara, 1996).

In the generic model, HF earthquakes reflect shear fracture of the country rock in the vicinity of volcanoes in response to increasing magmatic pressure. Since magma movement at depth may occur over large distances and long periods of time, the durations of HF swarms are long. At shallow depths of 1–3 km, several significant changes occur. First, gases begin to exsolve from the magma, changing its mechanical behavior, and hence its ability to transmit or reflect seismic waves. For example, exsolution of volatiles will increase the viscosity and lower the acoustic velocity. A seismic event generated by resonance of a magma-filled cavity would thus be richer in lower frequencies. Second, the magma may encounter groundwater, modifying the shallow hydrothermal system and removing some of the available magmatic heat

FIGURE 14 (a) Map of Kilauea Volcano and the east rift system showing earthquakes less than 15 km deep for the period September 1982 to January 1983. Shallow earthquakes (<5 km) are shown as crosses, and deeper earthquakes (>5 km) as squares; symbol size is proportional to magnitude. Note the concentrated shallow seismicity near Kilauea's summit and the more diffuse seismicity along the east rift zone. The deeper events occur mostly on a nearly horizontal fault. The 3 January eruption began near Puu Kamoamo. Zones free of earthquakes are shown with cross-hatching. Lines labeled A–A', B–B', etc. show cross sections. (b) Two cross sections (see map) showing the depth distribution of earthquakes near the summit and near the eruption site. (Modified from Koyanagi *et al.*, 1988.)

by conduction and advection. Most LF events and tremor originate at shallow depths, and several models for their origin involve fluids—water, magma, exsolved volatiles, or all three. Tremor caused by boiling of water is generally weaker than tremor involving magma movement. Third, open cracks are found above 3 km depth in the Earth, permitting venting of excess pressure. This may explain the relative quiescence after

the peak rate of a swarm as well as the inverse relation between high-frequency events and tremor.

The upper 1–3 km are small distances compared with depths to magma chambers (5–20 km) or crustal thicknesses (about 35 km). Thus, if vertical magma ascent rates are constant, then durations of LF event swarms and tremor sequences will be shorter than those of HF events simply because the

FIGURE 15 Summit tilt and daily number of earthquakes at Kilauea summit and upper east rift (UER) for the periods (a) July to December 1982 and (b) January to June 1983. Summit earthquakes are divided into short-period (SP) and long-period (LP) based on their waveforms. Note the summit swarms in September and December, and the strong UER swarm just before the eruption of 3 January 1983. Summit deflation typically accompanies the migration of magma into the east rift system. (From Koyanagi *et al.*, 1988.)

FIGURE 16 Unfiltered and filtered digital seismograms from station PV6 at Pavlof Volcano, 11 September 1996. Each record is for one day, one line per hour. The unfiltered seismogram shows only noise with variable amplitude. The lower seismogram was filtered to remove noise below 0.8 Hz and above 5 Hz. It shows the rapid onset of a swarm of small earthquakes that occurred a few days before the eruption.

FIGURE 17 Plot showing the reduced displacement of volcanic tremor during the 3½ months of the 1996 Pavlof eruptions. Stronger tremor accompanied more explosive phases of the eruption on 18 October, 4 November, 23 November, 10 December, and 27 December 1996.

FIGURE 18 Schematic diagram of the time history of a generic volcanic earthquake swarm model. Seismicity rates are shown along with the main types of events observed at each stage. Some ideas about dominant processes are presented at the bottom of the figure.

distances are smaller. Observations from a database of volcanic earthquake swarms (see Section 6.2) support this: LF swarms average 5.5 days and HF swarms 9.3 days. Deep earthquake swarms following eruptions probably reflect stress changes associated with partial evacuation of magma chambers deeper than 5 km.

Relative seismic quiescence following an initial seismicity peak occurred in 25% of a worldwide sample of 192 swarms (Newhall and Endo, 1987; J. Benoit, personal communication, 1994). While 25% quiescence may seem too low to be included in a generic model, it is included because of its importance in terms of eruption forecasting and identifying physical processes. Factors that may cause quiescence include strain hardening; high temperatures near the brittle–ductile transition; increased water content (e.g., groundwater) lowering effective stress; or a reduction in strain rate. It is common for low-frequency events and tremor to occur after seismicity rate peaks, during times of relative quiescence. This may be explained by gradual shoaling of the source, particularly magma interacting with groundwater or exsolution of volatiles.

Each volcano is unique in its seismic behavior, but the observations suggest that variations in a few parameters may account for the main differences. Minor variations in each of several parameters may greatly affect one observed parameter, such as swarm durations. The durations of earthquake swarms are characterized by a log-normal distribution with a mean of 5 days (Fig. 19). Precursory swarms are longer (mean = 8 days) and noneruptive swarms are shorter (mean = 3.5 days). No definitive correlations exist between the duration of a swarm and the size or type of eruptive activity. This is not

surprising given the ranges of sizes, rates, compositions, and types of structures observed.

6.2 Swarm Database as a Probabilistic Tool

Recently, parameters of 700 volcanic earthquake swarms have been compiled by Benoit and McNutt (1996) into an electronic database called the Global Volcanic Earthquake Swarm Database (GVESD). The database has one table of basic information on each volcano, such as type of lava, height, location, etc.; one table on eruptions, including volume, time of occurrence, type, etc.; and a table of swarm parameters such as duration, number of earthquakes, depths, magnitudes, etc. Using electronic search commands, it is possible to find all known cases of earthquake swarms that fit a particular profile. For example, we can search for the cases that last 3 weeks, have 60 events per day, and a largest event of $M=3.3$. The “answer” is a list of similar swarms that can then be analyzed to determine whether eruptions occurred, how long they lasted, and so on. Table 4 gives examples of three query answers that were obtained during the 1996 seismic crisis at Akutan volcano, Alaska, during which earthquakes up to $M=5.0$ occurred and more than 3000 events were felt. These answers are probabilistic in that they present a likelihood of something happening based on past occurrences. Such information is complementary to simultaneous efforts to determine and to constrain physical models of a volcano. The web site for the GVESD can be found at <http://www.avo.alaska.edu/dbases/swarmcat/GVESD.HTML>, and the database is also to be found on the attached Handbook CD, under directory \25McNutt.

TABLE 4 GVEDS Query Parameters(1) Swarms with $M > 500$ felt events: *Returned 4 entries*

Volcano	Date (d/m/y)	No. Felt	No. Detected	Activity
Unzen	15/5/84	519	10 544	No eruption
Usu	1/7/80	1 427	7832	During eruption
Usu	1/7/81	718	3694	During eruption
Tacana	7/5/86	1 000	4000	Before eruption

(2) Swarms with the largest shock $M \geq 5$ and swarms that preceded or accompanied eruptions: *Returned 10 entries*

Volcano	Date (d/m/y)	Duration (days)	$M_{\max}$
Tacana	15/12/85	72	5.0
Izu-Tobu	30/6/89	11	5.5
Sakura-Jima	10/1/14	3	5.2
Soputan	15/3/85	65	5.6
Usu	22/7/10	4	5.1
O-Shima	21/11/86	9	6.0
On-Take	15/8/76	1020	5.3
Miyake-Jima	13/10/83	3	6.2
Mt. St. Helens	20/3/80	59	5.0
Gorely	5/8/85	10	6.0

(3) Swarms with the largest shock $M \geq 5$ and swarms that had no eruption within 3 months: *Returned 9 entries*

Volcano	Date (d/m/y)	Duration (days)	$M_{\max}$
Rabaul	1/7/82	—	5.1
Rabaul	15/9/83	630	5.0
Rabaul	22/4/84	—	5.1
Unzen	15/5/84	270	5.7
On-Take	14/9/84	90	6.8
Norikura	7/3/86	—	5.1
Long Valley	4/10/78	570	5.7
Long Valley	7/1/83	67	5.2
Don Joao de Castro	21/11/88	1	5.8

6.3 Reduced Displacement Versus Volcanic Explosivity Index

Forecasting eruptions has received dominant focus as a goal of volcano seismology. However, characterization of eruptions in progress, including estimates of tephra volume, height of ash column, and end time of eruption, are other important parameters for physical understanding and for hazard mitigation, particularly regarding aviation. Progress has been made recently in estimating the Volcanic Explosivity Index (VEI of Newhall and Self, 1982) based on tremor reduced displacement (D_R) measured during eruptions (Fig. 20; McNutt, 1994). The computed relation is

$$\log_{10}(D_R) = 0.46(\text{VEI}) + 0.08 \quad (1)$$

FIGURE 19 Histogram of volcanic earthquake swarm durations. The horizontal axis is logarithmic, and the numbers shown represent the middle value of each bin. The data form a log-normal distribution with mean and median 5.5 and 7 days, respectively. (Modified from Benoit and McNutt, 1996.)

FIGURE 20 Volcanic tremor reduced displacement versus the Volcanic Explosivity Index (VEI) of Newhall and Self (1982). The plotted line is a regression fit to the data.

Reduced displacement is a method of normalizing volcanic tremor to a common scale. For body waves (e.g., P waves and S waves) the formula of Aki and Koyanagi (1981) is

$$D_R = \frac{A \cdot r}{2\sqrt{2}M} \quad (2)$$

For surface waves (e.g., Rayleigh waves, Love waves, and PL

waves) the formula of Fehler (1983) is

$$D_R = \frac{A\sqrt{\lambda r}}{2\sqrt{2}M} \quad (3)$$

where A = amplitude in cm peak-to-peak; r = distance from source to seismic station in cm; M = seismograph magnification at the tremor frequency; and λ = tremor wavelength in cm. The factor $2\sqrt{2}$ is the root-mean-square (rms) amplitude correction.

Such information is helpful for estimating plume heights and tephra volumes. The ends of eruptions can be estimated as coinciding with the end of strong tremor associated with eruptions. In many cases tremor declines more or less exponentially on a timescale of minutes to tens of minutes and returns to background levels. In some cases, eruptions of ash end but weak tremor continues for days in association with hydrothermal activity.

The ends of eruption sequences, which may last months to years, are more difficult to determine than the ends of individual eruption pulses which last a few hours to days. Generally volcanic tremor ceases altogether and the number of earthquakes per unit time decreases regularly. Volcanic earthquake swarms decline with a power-law decay similar to aftershocks, except that the timescale is often longer.

7. Conclusions

This chapter has discussed many general features of earthquake activity at volcanoes, and it has been shown that the activity varies widely. This is true because the volcanoes and their eruptions vary, and also because the stresses differ, and volcanoes have different geometries as well as combinations of rock, magma, water, and gases within them. Although seismic data are plentiful, the complexities of the volcanic environment often make interpretations difficult. Different processes can generate similar seismograms, and similar processes can generate different seismograms, although detailed diagnostics can often distinguish between them. This keeps volcano seismology challenging, but also suggests that seismology alone can be a somewhat limited tool.

In spite of this, volcano seismology has helped to answer some fundamental questions: (1) Where is the magma? Tomography and b value anomalies have identified large (km scale) magmatic or near-magmatic structures, while low-frequency events and volcanic tremor are associated with small-scale movement of magma or water. (2) What is “normal” earthquake activity at volcanoes? The case studies and general features sections showed that activity varies widely, but with a number of systematic trends. Successful separation of source, site, and path effects of seismograms helps to elucidate the causes of specific activity. (3) What will happen next? Understanding and modeling of physical processes and

study of many case histories are the two main tools used to evaluate this question. It is also possible, and indeed likely, that new high-quality data may lead to fresh insights about the new as well as older examples of earthquake activity at volcanoes.

1. Introduction

One of the principal goals and accomplishments of the seismographic monitoring of volcanoes is the tracking of earthquake hypocenters and the identification and interpretation of seismicity patterns that herald impending volcanic unrest (e.g., Koyanagi *et al.*, 1988; Harlow *et al.*, 1996). Traditional volcano monitoring networks are built to locate precisely microearthquakes that are often associated with magma transport. As with microearthquake monitoring networks in tectonically active regions, the ability to register and measure precisely the arrival times of the seismic first arrivals is a basic requirement.

In addition to the precise determination of earthquake hypocenters, it has long been a practice to use earthquake arrival times as constraints for seismic wave speeds. Aki and Lee (1976) first used seismic first arrival times to infer a 3D distribution of seismic *P*-wave speeds in central California. They used *P* wave arrival times from local microearthquakes in Central California, recorded on the northern California regional seismographic network, to image a low-velocity anomaly between the San Andreas and sub-parallel Calaveras faults. Since their study, many investigators have applied seismic tomographic inverse techniques to image targets in different regions and at different scales. Reviews of seismic tomographic imaging techniques and results are found in Nolet (1987) and Iyer and Hirahara (1993).

As we strive toward developing physically reasonable models of volcanic processes, it becomes increasingly important to resolve and account for details of internal volcanic structure. Arrival-time tomography is becoming

a commonly used technique for this purpose. It has been particularly successful in detailed imaging of large, complex volcanic systems, like Yellowstone (Benz and Smith, 1984), Hekla (Toomey and Foulger, 1989), Hawaii (Okubo *et al.*, 1997), and Mt. Etna (Villaseñor *et al.*, 1998).

Chouet *et al.* (1994), Lahr *et al.* (1994), and Power *et al.* (1994) describe aspects of the seismicity and sequence of activity culminating in the series of eruptions of Mt. Redoubt Volcano, Alaska, between December, 1989 and April, 1990. Spatial and temporal distributions of long-period (LP) and volcano-tectonic (VT) earthquakes were incorporated into inferences regarding the path along which magma traveled and the physical processes taking place during the eruptive sequence. See Chapter 25 by McNutt for a complete description of LP and VT earthquakes. A 3D tomographic study of Redoubt Volcano using seismic *P* and *S* wave first-arrival times (Benz *et al.* 1996) allowed features observed in the seismicity distributions to be associated with anomalies in V_P , V_S , and, in particular, V_P/V_S . With their tomographic imaging results and those of the earlier studies, Benz *et al.* (1996) were able to propose a detailed dynamic model of the Mt. Redoubt eruptions.

This chapter aims to provide insights into some of the key issues involving the inversion of first arriving *P*-wave data for 3D velocity structure and earthquake locations as applied to volcanic systems. Emphasis is placed on the need for thoughtful parametrization of the velocity model and selection of data, comprehensive error and resolution analysis, and comparison of the results with independent observations and constraints. The reader is referred to Pavlis and Booker (1980), Lees (1992), and Benz *et al.* (1996) for discussions on detailed aspects of the problem, including the inverse

formulation, error analysis, and applications to active volcanoes. A general overview of volcanic systems and seismological observations relevant to volcanic systems is provided by McNutt in Chapter 25.

We image the complex upper crustal structure beneath Mauna Loa and Kilauea and the south flank of Hawaii, using abundant well-located earthquakes recorded on the regional seismographic network operated by the Hawaiian Volcano Observatory (HVO) to invert first-arriving *P* phases to determine the 3D *P*-wave velocity structure and hypocenter locations. In this study, we use a robust and efficient method for calculating arrival times in structures with large local velocity variations (Podvin and Lecomte, 1991) and an efficient numerical inverse solver that incorporates smoothing constraints that enables us to optimally parameterize the subsurface structure.

2. Geological and Geophysical Framework for Hawaii

The proximity of active volcanism and faulting and large deformation rates makes the island of Hawaii an ideal place for studying both the dynamics of volcanism and earthquake generation. Located at the southeast end of the nearly 6000 km long Hawaiian-Emperor volcanic chain, Mauna Loa and Kilauea Volcanoes are formed by processes related to Hawaiian hot-spot tectonics (Clague and Dalrymple, 1987). Mantle-derived melts produced by the Hawaiian hot-spot migrate upward in the crust, where they erupt either in the summit calderas or along the east or southwest rifts forming these large, tholeiitic shield volcanoes. Buildup of the volcanic shield through episodic volcanism produces crustal deformation that is typically accommodated in gravitationally unstable normal-fault zones along the flank of the volcano. These fault zones periodically fail catastrophically, producing large submarine landslides (Moore, 1964; Moore *et al.*, 1989).

More than 30 years of detailed geophysical investigations have been conducted on the island of Hawaii in order to understand the origins and dynamics of oceanic volcanism. Starting with the first one-dimensional velocity model for the island of Hawaii (Eaton, 1962) seismic investigations have progressed through two-dimensional studies (e.g., Hill and Zucca, 1987) to 3D images of the crust and mantle (Ellsworth and Koyanagi, 1977) or detailed crustal imaging of the Kilauea volcanic system (Thurber, 1984) and the south flank of Hawaii (Rowan and Clayton, 1993).

Much of this previous work has focused on understanding the relationship between subsurface velocity structure and volcanism. However, volcanism and island tectonics, primarily observed in the Kaoiki and Hilina fault systems, are intimately linked as indicated by the proximity of active faulting, volcanism, and deformation. Swanson *et al.* (1976) demonstrate from geologic and geodetic observations that the entire south flank of Kilauea is moving upward and southward due to

episodic injection of magma into the rift system. Along the south flank of Kilauea, the Hilina fault system forms as a gravitational slump feature that is reacting to movement within and around, and deformation of, the volcanic system.

Mauna Loa and Kilauea are the two active volcanoes on the island of Hawaii, with Mauna Loa last erupting in 1984 while Kilauea has been in continuous eruption since 1983. Mauna Loa rises to an elevation of more than 4000 m, while Kilauea is situated along the southeast flank of Mauna Loa at an elevation of 1240 m. Both Mauna Loa and Kilauea are characterized by similar structural features; summit calderas, rift zones that extend away from the summits, and long linear zones of steeply dipping normal faults along the flanks of the volcano.

While noted for its prolific volcanism, the island of Hawaii experiences large earthquakes, as evident from the instrumentally recorded 1951 *M* 6.9 Kona earthquake, the 1975 *M* 7.2 Kalapana earthquake, the 1983 *M* 6.6 Kaoiki earthquake, and the 1989 *M* 6.1 Kalapana earthquake, all of which have been modeled and interpreted in terms of predominant seismic moment release along a subhorizontal faulting surface at or near the basal decollement (Ando, 1979; Eissler and Kanamori, 1987; Beisser *et al.*, 1994). How crustal deformation is accommodated between the basal decollement and the Kaoiki and Hilina fault zones is a topic of continuing debate (Swanson *et al.*, 1976; Lipman *et al.*, 1985). Lipman *et al.* (1985) argue that normal faults along the flanks of Mauna Loa and Kilauea extend through the crust to the basal decollement, while Swanson *et al.* (1976) argue that they are listric features that penetrate only a few kilometers of the crust.

We extend these studies by providing additional constraints on the 3D velocity structure, volcanism, and faulting. The 3D velocity results from this study are critical for constraining the location and size of volcanic sources that produce crustal deformation, for understanding the kinematics of magma migration and emplacement, and for providing insights into the interaction between the volcanoes and the development of the Kaoiki and Hilina fault zones. With more complete descriptions of previous geophysical and geological studies of the island of Hawaii available, for example, in Decker *et al.* (1987) and Tilling and Dvorak (1993), we focus our discussions more specifically on structural interpretations.

3. Seismicity and Data

A short-period seismic network that now consists of 52 stations has been continuously monitoring seismicity on the island of Hawaii since the early 1960s (Klein *et al.*, 1987). The majority of stations are located in areas of active volcanism or along the south flank of the island (Fig. 1). Most earthquakes occur beneath Kilauea, along the southwest and east rift zones, and within the Kaoiki and Hilina fault zones. Well-located earthquakes used in this study were selected from the seismicity catalog in the period 1986 to 1992 (Fig. 1). The distribution

FIGURE 1 Map of the island of Hawaii showing the study region (outlined by heavy line), key faults, vents, and calderas. Seismic stations used in the tomography are shown as filled triangles, while other permanent seismic stations are shown as open triangles. Also shown are the epicenters of the 5500 M 2.0 or larger earthquakes (open circles) located by the Hawaiian Volcano Observatory seismic network between 1986 and 1992. Elevation contour interval is 500 m.

of seismicity for this period is similar to the areal distribution of earthquakes located since the beginning of modern network operations in the early 1960s. We selected only earthquakes with a coda duration magnitude of 2.0 or larger, which are generally well-recorded over a large portion of the seismic network and have smaller timing errors due to the impulsive nature of the first P arrival. From a catalog of more than 5500 earthquakes M 2.0 or larger, we selected 4754 well-located volcano-tectonic earthquakes recorded by 42 stations that lie within the study area shown in Figure 1. To ensure that earthquake swarms in the vicinity of the volcanoes did not dominate the selection of events, we sorted earthquakes so that no two earthquakes were within 0.5 km of each other. Shown in Figure 2 are east–west (A–A') and north–south (B–B') cross sections of selected earthquakes in the study area.

Figure 2 shows that seismicity occurs to depths of about 40 km beneath Kilauea, but seismicity is not well distributed below about 20 km. Seismicity beneath Kilauea (distance = 42 km, A–A'; distance = 30 km, B–B') is well distributed over about a 10 km wide zone to depths of 20 km, while seismicity in the Kaoiki (distance = 20 km, A–A') and Hilina (distance = 18 km, B–B') occurs over a depth range of about 8–12 km. The areal and depth distributions of earthquakes are sufficient to adequately image the subsurface velocity structure to depths of 12–15 km beneath the south flank of Kilauea.

For our study area, the seismic stations are roughly 6 km apart with a station spacing of about 3 km within the summit region of Kilauea (Fig. 1). Earthquakes are well distributed to depths of about 10 km beneath the southwest and east rift zone

FIGURE 2 East–west (a) and north–south (b) cross sections showing the depth distribution of volcano-tectonic earthquakes used in this study. Only earthquakes that lie within ± 5 km of the cross-sections are plotted. See Figure 1 for location of cross sections.

of Kilauea and within the Kaoiki fault zone, and south of the Hilina fault zone (Fig. 2). Deeper seismicity to depths of 20 km within the study area is observed directly beneath Kilauea caldera (Fig. 2). Several steps were taken in our selection of the earthquakes to minimize model errors produced by errors in the observed data. We ensured that the earthquakes were well located by selecting events with a ratio of the earthquake focal depth to the closest station greater than 1.5, an azimuthal gap of less than 180° , and an initial arrival time RMS of less than 0.5 sec.

Using earthquakes with picking weights of 2 or less and recorded by 10 or more stations minimizes errors in the velocity model reconstruction due to poor earthquake locations and picking errors. The quality of the first arrival-time pick is determined using an analyst-defined integer weight between 0 and 4, with 0 being the highest-quality pick. The poorer-quality observations with a weight of 1 or 2 represent a small percentage of the total data used in our study. The distribution of arrival time observations by weight is 78%, 14%, and 8% for weights of 0, 1, and 2, respectively.

Topography in the study region ranges from near sea level to more than 4000 m above sea level, with station elevation ranging from near sea level to 4104 m. In our analyses, the top of the model is 5000 m above sea level and we adopt the convention that negative depths are above sea level and positive depths are below sea level.

4. Formulation and Implementation of the Inverse Problem

Vidale (1988) and Podvin and Lecomte (1991) developed finite-difference techniques that accurately and efficiently compute travel times in media with large, local velocity variations, a necessary requirement for determining the detailed 3D velocity structure and hypocenter locations in complex regions like Hawaii. Benz *et al.* (1996) incorporated the finite-difference formulation of Podvin and Lecomte (1991) into a procedure that simultaneously inverts for 3D velocity structure and hypocenter locations. The reader is referred to Benz *et al.* (1996) for details on the formulation and implementation of the forward modeling and inversion algorithms used in this study.

Simultaneous inversion for velocity structure and hypocenter locations is computationally expensive, while decoupled inversion for the slowness perturbations and hypocenter locations is easily and efficiently implemented. For our application, we solved both the coupled and decoupled velocity structure–hypocenter location problem and found no discernible differences in the final 3D velocity models and hypocenter locations on the scales that we will interpret. Each application will dictate whether such an approach is justified. In either case, the system of equations used to compute the perturbations to the slowness model are solved using an efficient LSQR inverse solver (Paige and Saunders, 1982). Smoothness constraints are added to the system of equations to control the degree of model roughness. Tests are done to determine the appropriate weighting for the smoothness constraints that produce relatively smooth velocity models without severely affecting the minimization of the data misfit.

The hypocenter partial derivatives needed to determine the perturbations to the hypocenter location are computed using a standard approach (Benz and Smith, 1984), while the earthquake hypocenters are determined using an SVD algorithm and damped least squares. Both the slowness model and hypocenters are updated and the procedure is repeated until there is no appreciable reduction of the RMS of the travel time residuals with additional iterations.

Inversion for the velocity structure and hypocenters requires a starting velocity model and initial earthquake locations. In our application to the island of Hawaii, the velocity model is parameterized as constant-velocity cells that are $2 \times 2 \times 1$ km in the horizontal and vertical directions,

respectively. Travel times are calculated on a finer 0.5 km square grid of cells, interpolated from the inversion grid, in order to maintain a travel time precision better than ± 0.05 sec. The total number of inversion cells in the model is $46 \times 28 \times 26$ in the east–west, north–south, and vertical directions, respectively. Rays are traced from source to receiver through the travel time grid by back projection along the isochrons using a procedure developed by Hole (1992). Station elevations are correctly modeled by locating the station at its proper location in the model.

4.1 Model Resolution and Error Estimation

The geometry of sources and receivers, quality of observations, and parametrization of the model all contribute to errors in the reconstruction of the subsurface velocity structure. Errors due to model parameterization include inappropriateness of the starting velocity model, coarseness of model grid spacing, accuracy of the raytracing, and corrections for topographic effects like station elevation. Numerous tests are done to find an appropriate combination of sources and receivers and model parameters that produce a robust final 3D velocity structure. It is important to find an optimal inversion grid spacing and starting velocity model. Tests are also necessary to determine how changes in the model parameters translate into model uncertainty. The LSQR solver used here does not allow for the direct computation of formal resolution and model uncertainty. Consequently, resolution analysis is done empirically by recovering a checkerboard input velocity model using synthetic arrival time data that simulates the source and receiver geometry and estimated data error. We provide examples of various tests that were done to insure a robust 3D velocity model of the south flank of the island of Hawaii.

Model resolution is strongly affected by the quality of ray sampling throughout the velocity model. The degree of ray sampling is controlled primarily by the geometry of the sources and receivers and grid spacing of the velocity model. Identifying what portions of the model are well-sampled and how well structures can be resolved throughout the model space is achieved by inversion of synthetic arrival time data based on a checkerboard velocity model. A checkerboard velocity model used here is defined as alternating high- and low-velocity bodies that are 5 km on a side with velocities varying by $\pm 10\%$ relative to a 6.0 km sec^{-1} reference velocity model. Velocities are varied smoothly between the high- and low-velocity zones so that the peak amplitudes of the anomalies are 3.0 km wide. Synthetic arrival times are computed for the checkerboard velocity using the observed source and receiver geometry. The checkerboard is then reconstructed by inverting the synthetic *P*-wave arrival times starting with a homogeneous velocity model of 6.0 km sec^{-1} .

Shown in Color Plate 7 are comparisons of the reference checkerboard model and velocity reconstructions at selected

depths and along an east–west cross section. The plate shows that for the 7–8 km depth about 90% or more of the absolute amplitude of the high- and low-velocity anomalies is recovered. For depths shallower than 2 km and deeper than about 12 km, results are best beneath Kilauea caldera, the Kaoiki fault zone, and portions of the southwest and east rift zones. The cross section in the plate shows that the checkerboard model is reproduced to depths of 15 km beneath the south flank of the island of Hawaii. The cross section also shows the effects of smearing along the edges of the model and at deeper depths where there are fewer rays that generally travel in one direction. Smearing causes anomalies to be elongated along the direction of the ray. Results show that for depths of 2–12 km, where most of the seismicity is concentrated, features with wavelengths of about 3–5 km can be imaged for much of the model space. Recovery of the model degrades for shallower (< 2 km) and deeper depths (> 12 km) due to inadequate ray sampling. The exception being beneath Kilauea caldera where sources extend to depths of 20 km.

Another form of synthetic testing is reconstruction of individual synthetic anomalies located at critical positions within the model space. Reconstruction of individual anomalies illustrates the degree of resolution at specific depths and the effects of model smoothing and ray smearing of relatively small model features. In the example shown in Figure 3, a small $2.5 \times 2.5 \times 2.5$ km high-velocity body (10% relative to a reference velocity of 6.0 km sec^{-1}) is centered at a depth of 4.5 km beneath Kilauea caldera. Synthetic arrival times are calculated for this velocity model and the observed source and receiver geometry and then inverted using a homogeneous starting velocity model of 6.0 km sec^{-1} and an inversion and raytracing grid spacing of 0.5 km. The square anomaly shown in Figure 3 was placed at the approximate location of an unusually high-velocity body ($\sim 8.0 \text{ km sec}^{-1}$) with comparable dimensions imaged by Thurber (1984) and Rowan and Clayton (1993).

Figure 3 shows that the lateral and vertical dimensions of the anomaly, which is half the dimension of the anomalies in the checkerboard model, are well recovered in the inversion results. Approximately 70% of the anomaly's amplitude is recovered in the synthetic test. The absolute amplitude of the recovered anomaly will be strongly affected by the degree of model smoothing applied in the inversion and resolvability of the anomaly. For the case shown here, which applies to the observed data, smaller scale features at upper-crustal depths beneath Kilauea are well-resolved and the smoothing used is optimal for recovering most of the anomaly's amplitude without appreciably blurring the anomaly with the background velocities. Recovery of the anomaly's size and shape indicates negligible ray smearing at these depths. These results, combined with the checkerboard test shown in Color Plate 7, demonstrate that small-scale features on the order of a few kilometers in dimension are recoverable in the upper

FIGURE 3 Map view of a synthetic velocity model (a) showing the location of a small $2.5 \times 2.5 \times 2.5$ km velocity anomaly ($+10\%$ relative to a background velocity of 6.0 km sec^{-1}) and the synthetic reconstruction of the anomaly (b). East-west cross section A–A' of the synthetic velocity model (c) and the synthetic reconstruction of the anomaly (d). See the text for a description of the generation of the checkerboard velocity model and calculation of the synthetic arrival times.

12–15 km of the crust with the existing seismic network and phase data.

The initial one-dimensional velocity model used in the inversion of the observed data is similar to that used by the HVO in its routine earthquake location procedures (Fig. 4). HVO's velocity model was determined by one-dimensional inversion of arrival time data for earthquakes and stations in the vicinity of Kilauea (Klein, 1981). For depths shallower than about 2 km, the one-dimensional velocity model used in this study is faster than the standard location model, but it has about the same gradient and velocity between 5 and 17 km depth. Our higher upper-crustal velocity model probably reflects higher average velocities in the shallow crust for the study region as compared to shallow upper-crustal velocities in the vicinity of Kilauea. Shown in Figure 4 are different one-dimensional velocity models that we tested for use in this study. These models ranged from the velocity model of Klein (1981) with very slow, shallow velocities and a high-velocity gradient in the upper crust (thin, solid line; Fig. 4) to modified versions of the HVO model. The modified HVO models (dashed lines; Fig. 4) differ primarily by having different upper-crustal (<5 km depth) velocities and gradients, but general follow the HVO model for depths greater than 5 km. While our velocity model (thick, solid line; Fig. 4) had the smallest initial arrival time rms, results based on the all of the models produced comparable final arrival time rms and similar velocity variations within the study area.

Previous tomographic studies of Kilauea (Thurber, 1984; Rowan and Clayton, 1993; Okubo *et al.*, 1997) have imaged an extremely high-velocity anomaly (~ 7.8 – 8.0 km sec $^{-1}$) at a depth of 5 km beneath Kilauea caldera. Our 3D velocity models based on each of the starting one-dimensional velocity models shown in Figure 4 all show the same feature. In addition, the absolute velocity of the anomaly varies by less than 0.2 km sec $^{-1}$ between models. Within the upper 12 km of

the crust, larger anomalies that will be discussed later in this chapter are observed in all inversions based of the starting one-dimensional velocity models shown in Figure 4. These results, combined with the synthetic modeling (Color Plate 7 and Fig. 3) and other tests results (not shown here) using different smoothing parameters and grid spacing, indicate that model uncertainties are ± 0.2 km sec $^{-1}$ for depths between about 2 and 12 km and increase to ± 0.3 km sec $^{-1}$ for deeper depths. Uncertainties in the velocities at shallower depths (< 2.0 km sec $^{-1}$) are difficult to quantify due to the poor sampling and large variations in near-receiver velocity structure.

5. Three-Dimensional P-Wave Velocity Model for Hawaii

After 12 iterations, tomographic inversion for the 3D velocity structure resulted in a 77% reduction in the arrival time RMS from a starting residual of 0.39 sec. Shown in Color Plate 8 are map views of the 3D *P*-wave velocity structure at selected depths between 1 and 15 km. Layers shown in the plate are 1 km thick, and cells not sampled by any ray are shown as white. For much of the study area, the resulting 3D velocity structure is consistent with the known geology and previous crustal imaging studies (Hill and Zucca, 1987; Thurber, 1984; Rowan and Clayton, 1993). Development of the Hawaiian shield is primarily from basaltic magmatism; consequently, compositional differences in the rock types are small. Differences in the constitutive properties of the rock and observed *P*-wave velocities are primarily due to hydrothermal alteration, variations in temperature and changes in the porosity or density of microcracks. We will follow the example of Hill and Zucca (1987) and use their table of rock velocities versus rock type in describing the subsurface velocity structure.

The most prominent upper crustal velocity anomaly observed in the inversion results is a northeast-trending high-velocity body that ranges from 5.8 km sec $^{-1}$ at 3 km depth to 6.8 km sec $^{-1}$ at 7 km depth beneath the south flank of Mauna Loa (Color Plate 8). Adjacent to and southeast of this high-velocity region, the Kaoiki fault zone is observed as an approximately 14 km wide zone of low velocities that range from about 3.8 km sec $^{-1}$ at 0 km depth to 5.6 km sec $^{-1}$ at a depth of 5 km. High upper-crustal velocities along the southeast flank of Mauna Loa are consistent with intruded pyroxene gabbros or sheeted-dikes, while relative low velocities beneath the Kaoiki fault zone probably represent highly faulted shallow crust. Prior to the inception of Kilauea, Lipman (1980) argues, the Kaoiki fault zone formed as a gravitational slump feature on the southeast flank of Mauna Loa as the shield grew. High rates of microseismicity within the Kaoiki fault zone and the *M* 6.6 1983 Kaoiki earthquake suggest a continuing development of the fault system.

FIGURE 4 The initial one-dimensional *P*-wave velocity model used in the 3D velocity inversion (bold, solid line) and other one-dimensional *P*-wave velocity models tested for use in the inversion.

The velocity structure beneath Kilauea summit is best described as highly complex with velocities ranging from 6.0 km sec^{-1} at 3 km depth to 7.2 km sec^{-1} at a depth of 11 km. Within this region, velocities reach as high as 7.7 km sec^{-1} at a depth of 5 km beneath the south rim of the caldera. Thurber (1984) observed velocities near 8.0 km sec^{-1} at similar depths in his local tomography study of Kilauea. Such high velocities at shallow depths are likely ultramafic cumulates at the core of the conduit system. From about 12 km depth to the bottom of our model at 20 km, a roughly cylindrical relative low-velocity anomaly is observed beneath Kilauea that broadens with depth. This is illustrated at 15 km depth (Color Plate 8) where a velocity of 6.8 km sec^{-1} beneath Kilauea is about 6% slow relative to average layer velocities of 7.2 km sec^{-1} . These slower upper-mantle velocities likely reflect the influence of local, higher temperatures associated with the hot-spot and not compositional or porosity differences that are more prominent at shallow depths. Beneath Kilauea, the Moho is estimated at about 15 km depth and rocks at this depth are likely ultramafic cumulates (Hill and Zucca, 1987). A local zone of high temperatures due to the presence of a mantle hot-spot will produce locally slower upper-mantle/lower-crustal velocities.

Both Thurber (1984) and Rowan and Clayton (1993) imaged a small, shallow magma reservoir beneath the Kilauea summit caldera at depths between 0 and 2 km. Our results reveal velocities of $4.6\text{--}4.8 \text{ km sec}^{-1}$ at similar depths beneath the summit, which are only slightly slower than velocities of $5.0\text{--}5.2 \text{ km sec}^{-1}$ outside of the caldera region. Our results are not conclusive in defining a shallow low-velocity magma reservoir. It is likely that the smoothing constraints used in the inversion attenuate small low-velocity zones that are on the order of one or two inversion cell dimensions. Test results showed that we were able to reconstruct shallow low-velocity anomalies in the vicinity of Kilauea to within $\pm 0.2 \text{ km sec}^{-1}$ with wavelengths of about 3–5 km. The shallow magma reservoir beneath Kilauea is smaller than we are able to resolve with the present distribution of permanent stations. In 1995, approximately 100 temporary seismic stations were deployed around Kilauea summit (McNutt *et al.*, 1997) in order to image the shallow structure beneath Kilauea caldera. High-resolution seismic tomography results from that experiment (Dawson *et al.*, 1999) reveal a small, shallow magma reservoir beneath Kilauea caldera.

The southwest rift zone is underlain by high-velocity material between 1 and 9 km depth, where velocities range from 5.4 to 7.0 km sec^{-1} . High velocities are uniformly distributed along the length of the rift zone in the depth range 1 to 5 km, but lie primarily between Puu Koa and Mauna Iki at depths of 7–9 km. The zone of high velocities broadens laterally away from the rift zone with increasing depth from a few kilometers, near the surface, to approximately 12 km wide at depths greater than 5 km. A widening rift zone with depth is similar to that observed by Hill and Zucca (1987), who modeled the rift zones using refraction travel time

data as a wedge of high-velocity material, which they interpreted as pyroxene or olivine gabbro sheeted-dike complexes. Beneath the east rift zone, high velocities of 5.6 to 6.8 km sec^{-1} are observed in the depth range from 1 to 8 km, respectively. For much of the east rift zone, high velocities are only observed at depths shallower than about 4 or 5 km. For the depth range 5 to 7 km, high velocities are observed only beneath Makaopuhi. Unlike the southwest rift zone, relative low velocities of 5.8 km sec^{-1} are observed beneath the east rift zone in the depth range 8–11 km between Kalalua and Heiheiahulu.

High velocities between 6.8 and 7.0 km sec^{-1} are observed in the depth range 4–6 km between the southern edge of Kilauea caldera and the Koaie fault zone. The Koaie fault zone is described by Swanson *et al.* (1976) as an east–west trending, tearaway zone connecting the rift zones that separates the south flank from the volcanic edifice. Eruptions rarely occur within the Koaie fault zone, but the 3D velocity results do suggest that dike emplacement occurs in the fault zone as seen by high velocities of about 6.5 km sec^{-1} at upper-crustal depths of 4–6 km. This is consistent with observed magma injection into the Koaie fault zone following the 1973 east rift zone eruption, where spreading of the rift zone produced dilation in the Koaie fault zone and subsequent dike-intrusion (Koyanagi *et al.*, 1973). An upper-crustal dike complex beneath and north of the Koaie fault zone is consistent with the deformation and modeling results of Borgia (1994) and Clague and Denlinger (1994), who argue that a shallow ductile zone is required beneath the Koaie fault zone to explain in part south flank deformation observations.

Complex, high velocities observed in the upper 8–9 km of the crust beneath the rift zones and Kilauea and a simpler, roughly cylindrical-shaped anomaly below Kilauea at depths greater than about 12 km, are consistent with the mechanical/structural model of Ryan (1988). Ryan (1988) describes the magma system as a conduit-like feature that raises from the mantle to shallow depths beneath Kilauea. Above about 10 km depth, the magma system spreads out laterally, becoming a zone of sheeted-dike complexes beneath the rift zones with the main conduit remaining beneath Kilauea. Seismicity reveals the conduit to remain nearly vertical beneath Kilauea to depths of 20 km, where it then broadens and dips gently southward in the upper mantle at depths of 20–60 km (Klein *et al.*, 1987).

The largest low-velocity feature observed in the tomographic study is beneath and south of the Hilina fault zone where velocities range from about 4.5 km sec^{-1} , near to the surface, to 5.8 km sec^{-1} at 9 km depth. Interpretation of deformation, bathymetry, and seismicity observations by Denlinger and Okubo (1995) argue that the Hilina fault system must be a through-going feature connected to the basal decollement in order to explain the scales of deformation of the flank and subaerial tectonics. These low velocities are likely due to increased abundance of microcracks from active

FIGURE 5 (a) Map showing the location of selected cross sections (b–d). Cross sections of the 3D *P*-wave velocity structure. Cross-sectional width is one cell dimension, or 2.0 km. Velocity contours are in km sec⁻¹.

faulting and slumping of the entire volume from the surface to the basal decollement. Laboratory studies (Christensen, 1979) have shown that increased microcracking strongly reduces *P*-wave velocities in the upper crust. Below approximately 11 km depth, velocities beneath the Hilina fault zone do not appear to be anomalous. The south flank velocity variations suggest that the Hilina fault zone penetrates the entire volcanic pile down to, but not below the basal decollement, thought to be at 9–10 km depth.

The complex velocity structure beneath the south flank of the island of Hawaii is well illustrated by selected cross sections through our 3D *P*-wave velocity model (Fig. 5). Cross-section A–A' shows the velocity structure along a line that cuts through Mauna Loa and the Kaoiki fault zone. High velocities of 7.0 km sec^{-1} are observed beneath the south flank of Mauna Loa in cross section A–A', while lower upper crustal velocities are observed to depths of 6 km beneath the Kaoiki fault zone. The complexity in the velocity structure beneath Kilauea is clearly seen in cross section B–B' (distance = 33 km). Velocities as high as 7.7 km sec^{-1} are observed at depths between 5 and 6 km, with most of the structure beneath Kilauea defined by velocities higher than about 6.8 km sec^{-1} between depths of 5 and 12 km. Southward of the Hilina fault zone, velocities are offset downward to depths of about 9 km, showing the depth extent of faulting and direction of fault motion. Cross section C–C' shows the high velocities of 7.0 km sec^{-1} beneath the flank of Mauna Loa (distance = 24 km), complex high-velocity structure beneath Kilauea (distance = 44 km), and high velocities of 6.6 km sec^{-1} beneath the east rift zone (distance = 58 km).

6. Relocated Seismicity

The average change in the hypocentral location of the 4796 earthquakes relocated in the 3D velocity model is 0.5 km horizontally and -1.3 km vertically. Changes in origin-time average $+0.1 \text{ sec}$. Few significant differences are observed between the initial and relocated seismicity for depths less than 5 km (Fig. 6). The relocated seismicity at these depths does not provide any clearer definition of shallow structures. Map views of the initial and relocated seismicity at depths between 5 and 13 km (Fig. 6) show that seismicity between Mauna Loa and Kilauea concentrates in tighter clusters and shows a narrower distribution laterally. Relocated seismicity south of the east rift zone separate into more discrete zones of seismicity, presumably reflecting zones of stress concentration near centers of magma emplacement. For depths greater than 13 km, the initial and relocated seismicity is generally diffuse beneath Kilauea caldera.

Comparison of initial and relocated seismicity (Fig. 7) along a NW–SE cross section centered on Kilauea shows the relocated seismicity beneath Kilauea to be more broadly distributed from about 5 to 20 km depth. This zone of seismicity

is also systematically shallower. Generally, the relocated seismicity at shallow depths (-1 to 5 km) halos a relative low-velocity region, which is the preferred location of a shallow magma chamber (Thurber, 1984). Rapid changes in the space–time seismicity patterns in Hawaii (Klein *et al.*, 1987) and the relatively minor spatial changes seen in the relocated seismicity (Figs. 6 and 7) make it difficult for us to use our results to better understand the seismo-volcanic framework of Hawaii. Detailed analysis of the space–time variations of the entire relocated seismicity catalog is necessary for providing a better understanding of Hawaii seismicity and its relationship to active volcanism, which is beyond the scope of this chapter. Importantly, relocating the seismicity in this study is critical for minimizing systematic errors in the observed data due to earthquake mislocations.

7. Discussion

A strong correlation is observed between the 3D *P*-wave velocity structure and the observed magnetic intensity (Hildenbrand *et al.*, 1993) and gravity (Kinoshita *et al.*, 1963) of the island of Hawaii. The southwest and east rift zones, which are underlain at shallow depths by high velocities in the tomography results, are observed as zones of higher magnetic intensity and higher gravity. Hildenbrand *et al.* (1993) interpret high magnetic intensity anomalies in the rift zones as due to shallow dike complexes with magnetization highest at the core of the rift and decreasing laterally away from the rift due to hydrothermal alteration of the intruded material. High velocities in the rift zones suggest that the rocks are relatively dense, which produces a larger gravitational attraction and corresponding anomaly. The Hilina and Kaoiki fault zones are identified as zones of low velocity, low magnetic intensity, and low gravity. Hildenbrand *et al.* (1993) interpret relative low magnetic intensities in the Kaoiki and Hilina fault zones as due to alteration products from groundwater and hydrothermal activity. Lower velocities underlying the Kaoiki and Hilina fault zones are interpreted as highly fractured and perhaps chemically and thermally altered zones of lower density, consistent with Hildenbrand *et al.* (1993).

Constraints on the geometry of zones of magma intrusion and the depth extent of active faulting are important for understanding deformation of the south flank of Hawaii and the potential and size of catastrophic failure of the south flank. An interpretation of the Hilina fault zone based on geomorphic and geodetic observations (Swanson *et al.*, 1976) suggests that the fault zone bottoms into the hyaloclastites and subaerial lava flows at depths of 2–3 km. Lipman *et al.* (1985) and Denlinger and Okubo (1995) argue that the fault zone cuts the volcanic pile through to the basal decollement. Relative low velocities to depths of approximately 9 km south of the surface expression of the Hilina support the more recent interpretations.

FIGURE 6 Map views of the initial earthquake locations (a–c) and earthquake locations (d–f) based on relocation in the 3D *P*-wave velocity structure (earthquakes are plotted as circles). The seismic stations (triangles) used to monitor seismicity and major faults, fissures, vents, and calderas are shown for reference.

The 1983 *M* 6.3 earthquake beneath the Kaoiki fault zone and a general increase in earthquake swarms along the south flank of Mauna Loa demonstrate that the Kaoiki fault zone is still active. While the seismicity is generally diffuse between Mauna Loa and Kilauea, shallow seismicity does not correlate with the northeast trend of the Kaoiki fault system. This is likely a consequence of the superposition of the crustal strain due to influence of Mauna Loa and its associated flank deformation and that produced by Kilauea.

The 3D velocity model shows the velocity structure beneath Kilauea to be defined as a complex, near-vertical high-velocity conduit approximately 8 km wide between depths of 4 and

12 km. From about 14 km depth, near the Moho, to the base of our model at 20 km, the conduit remains near-vertical but broadens into a relative low-velocity zone with a width of approximately 14 km. At lower crustal and upper mantle depths, a relative low-velocity conduit shows the thermal effects of the hot-spot, where the conduit is defined as a zone of weakness intruded by hot mantle and lower crust partial melt. Using seismicity to depths of 40 km, tomographic results not presented here show the conduit to be a persistent feature that broadens further, dipping gently southward in the upper mantle.

Results from this tomographic study show that high velocities underlying the south flank of Mauna Loa are interpreted

FIGURE 7 Northwest-southeast cross section of the initial earthquake locations (a) and earthquake locations (b) based on relocation in the 3D P -wave velocity structure (earthquakes are plotted as circles). See Figure 6 for location of the cross section. Cross-sectional width is one cell dimension, or 2.0 km. Velocity contours are in km sec^{-1} .

as a zone of dense sheet-dikes that have fed previous Mauna Loa eruptions. The Kaoiki fault zone, lying between Kilauea and Mauna Loa, is a zone of normal faults formed by southward migration of the south flank of Mauna Loa prior to the inception of Kilauea volcanism. Much of the flank motion is now being taken up on the Hilina fault system, which lies on the south flank of Kilauea (Swanson *et al.*, 1976). The interaction between Kilauea volcanism and motion on the Hilina fault system is a present-day analogue of the growth of Mauna Loa and the Kaoiki fault system (Lipman, 1980). Beneath Kilauea, the magma conduit is described as a near-vertical upper-mantle and crustal feature interpreted as a sheeted-dike complex that extends as far southward as the Koae fault zone. The Hilina fault system extends to the basal decollement near a depth of 9–10 km.

8. Conclusions

Three-dimensional tomographic imaging of Mauna Loa and Kilauea Volcanoes shows the presence of high-velocity

ultramafic rock beneath the volcanoes and the southwest and east rift zones. These high velocities correlate with zones of high magnetic intensity and high gravity and are interpreted as ultramafic cumulates associated with the melt observed at the surface. Episodic injection of new material from beneath produces deformation and inflation of the Kilauea summit and rift zones that destabilizes the upper crust, producing the normal faults observed in the Hilina fault systems. Tomographic imaging reveals that the Kaoiki and Hilina fault zones are observed as relative low-velocity zones that extend to depths of 9–12 km, suggesting that these fault zones penetrate to the basal decollement. This has important implications with regard to long-term stability of the south flank of the island and constraints on the initiation of sudden and mass debris flows off the south flank of the island of Hawaii.

Acknowledgments

This research was supported by the US Geological Survey National Earthquake Hazards Reduction Program and the Volcano Hazards Reduction Programs. Roger Denlinger, Dal Stanley, Fred Klein, Steve McNutt, Wim Spakman, and an anonymous reviewer provided thoughtful comments that improved this manuscript.

Marine Seismology

Earthquake Research Institute, The University of Tokyo, Japan

1. Introduction

Seismology is the study of earthquakes and associated phenomena, most notably the physical properties of the Earth's interior. Marine seismology is simply seismology in which the observations are made at sea. Because oceans cover most of the plate boundaries, earthquakes occur mostly beneath the sea floor. This provides a strong incentive to observe and study earthquakes at sea near the sources. Modeling seismic velocity structure provides a basic scheme for understanding the ongoing active processes as well as the history. Global-scale modeling of the Earth's deep interior is presently limited by the lack of broadband seismic data from the ocean floors.

In this chapter we will discuss how these aspects of marine seismology have been tackled by marine seismologists. Our emphasis will be on marine seismological studies at convergent margins. Chapter 55 by Minshull is an important complement to this chapter, since it deals with seismic structures of oceanic crust in general.

Making observations at sea is no easy task, especially for seismic data, which may require an observational window of a large dynamic range of more than 24-bit (144 dB) and wide frequency band from 10^{-4} to 10 Hz, or higher for artificial sources, and a long time span. Seismic sensors of the same type as used on land are usually encapsulated in pressure housings to be emplaced on sea floors often at as deep as 7000 m water depth. Data are recovered by retrieving the data recorder at sea or by telemetering to land via sea-floor cable. Power is supplied by batteries unless cable is available. These factors restrict the capacity and quality of the data. The instrumental challenge of marine seismology has been to overcome these difficulties.

2. Brief History

A brief history of observational aspects of marine seismology is given in this section. We focus here on sea-floor seismic

observations that allow us to record both *P* and *S* waves. We will see later that seismic reflection techniques, which grew from oil prospecting efforts, are now indispensable in studying seismic velocity structures.

One of the earliest observations on the sea floor was made in 1937–1940 by the group at the Lehigh University of Pennsylvania, USA (Ewing and Vine, 1938) [Note: Maurice Ewing joined the Columbia University in 1944 and established the Lamont Geological Observatory in 1949.] Since then, groups in the United States, USSR (now Russia), Japan, and others have made efforts in developing ocean-bottom seismographs (OBSs). At first, sea-floor noise measurements were the main objective in order to check the feasibility of sea-floor observations. However, it was difficult to construct a good enough instrument to record the noise level.

A major success of OBS came in the 1970s when a very long profile was shot in the western Pacific to study the deep structure of the oceanic lithosphere (Asada and Shimamura, 1979). This method of employing several OBSs to cover a 1000 km scale distance proved successful in the early days of trying to verify the plate tectonics theory, given that signals from dynamite shots could be recorded at far distances. These results strongly suggested the existence of a large-scale lateral heterogeneity and anisotropy, related to the origin of the lithosphere and subsequent spreading history. However, the seismic characteristics of the oceanic lithosphere are still far from well understood.

OBS technology advanced through the 1970s at several institutions, including more European countries. Each effort employed its own strategy as there were many objectives and choices to be made: geophone or hydrophone, digital or analog, continuous or programmed recording, tethered or pop-up (timed or on-command) for recovery, cassette or open reel, FM or direct recording, and so forth.

Important marine seismological results in the 1960s through the 1970s were mainly not obtained from OBSs, which were essentially in the instrumental development stage. Key results, such as crustal structures around the globe, or uppermost mantle

Pn velocity anisotropy were obtained from refraction seismology by two-ship experiments or sono-buoy systems shooting explosives or airguns (see, e.g., Suyehiro, 1988, for a summary).

In the 1980s, pop-up OBS technology matured in terms of getting the data back to become the main force in crustal structure studies. Tens of OBSs could be deployed for each experiment (e.g., Ewing and Meyer, 1982; Iwasaki *et al.*, 1990).

At the same time, further efforts continued to expand the fidelity of the recordings. One such direction was to utilize deep boreholes drilled by the Deep Sea Drilling Project (DSDP) or its successor the Ocean Drilling Program (ODP) (Adair *et al.*, 1984). The sensors used in these experiments were of short-period type. Their sub-sea-floor data showed improvement in S/N ratio over sea-floor records by up to 30 dB, with better improvements for horizontal components.

The recent direction of marine seismology in the studies of crustal scale has been to utilize as much seismic information as possible, acquiring both reflection and refraction data; that is, to utilize a wide range of incidence angles of seismic waves. For example, in the Japan Sea, the sea bottom is flat in the basin but has a very rugged basement structure. Without the definition of this rugged basement by the reflection method, the perturbation caused by this would propagate to deeper depths if modeled using only the refraction data. In the following section we will see the present status of marine seismology.

3. Seismological Structures

In this section we overview how marine seismology aids our understanding of the tectonics and dynamics of the Earth using convergent margin environments as case studies. By seismological structure, we refer to both seismic activities and seismic velocity structures. How these two results from seismology can be physically connected is an important and unresolved question.

For larger-scale problems we need to obtain the physical properties of the interior of the Earth in terms of temperature, density (pressure), and viscosity (fluid/melt percentage) distribution, since the dynamic equations require these parameters for modeling the Earth. However, we will concentrate on crustal-scale phenomena in this section, since they have been the only attainable targets until very recently.

How the oceanic crust is formed and evolves through time and eventually returns to the mantle is clearly one of the most important questions for which marine seismology can provide critical information. These problems are dealt with in Chapter 55 by Minshull and therefore, are not discussed here. Other important problems for marine seismology include understanding the dynamics of devastating earthquakes at subduction zones, and understanding the structures of oceanic island arcs, plateaus, or backarc basins.

Before the 1970s, marine seismology was really unable to resolve unequivocally the action of plate tectonics. During the

last decade or so, improvement of the sensors and the use of many sensors have allowed us to image 2D structures with unprecedented accuracy. Before then, 2D models had been constructed from 1D models from seismic profiles shot in the direction of least lateral structural change. One of our remaining goals is 3D imaging of 3D structures over widely different scales, such as for seamounts or for the deep roots of hot-spots.

Seismic reflection studies and seismic refraction studies have long been made as if they were targeted at two independent structures. Reflection studies often produced results much higher in spatial resolution but limited in depth penetration, while the opposite was often the case for refraction studies. Currently the two kinds of data complement each other to yield a more comprehensive view of the seismic structure. MCS (multichannel seismic) data provide detailed laterally heterogeneous sedimentary structure, which helps correct the refraction data to better constrain the deeper structure. Refraction velocities help to better image the MCS seismic sections.

Just as land seismology must also consider geological or geochemical data in order to infer tectonics and history of any target, marine seismology must also try to incorporate such knowledge. We are now in a much better position than before since, in addition to sea-floor sampling tools that have been in existence for a long time, there are submersibles, swath bathymetry devices, deep coring tools, and so on.

3.1 Plate Subduction Zones

As oceanic plates subside underneath the overriding plates, earthquakes occur and volcanoes erupt. Their modes of occurrence differ in different zones. Plate subduction is closely linked to island arc growth and backarc basin opening. Detailing the characteristics of this variety to understand how and why these processes take place is a major target of marine seismology.

Large earthquakes that occur at plate subduction zones are mostly interplate thrust events, the two largest in the 20th century being the Chilean earthquake in 1960 (M_W 9.5) and the Alaskan earthquake in 1964 (M_W 9.2). The oceanic plates thrust against continents or island arcs at speeds of the order of centimeters per year (10 km My^{-1}), and accumulate displacements to provide meters of earthquake slip over a hundred-year time scale. Thus these interplate earthquakes are explained by the plate tectonics theory. However, only a limited width of the plate boundary experiences such slip and, furthermore, even within that zone less than 100% of the slip is taken up by earthquakes. Such inferences are available from teleseismic observations alone. Where marine seismology can play a major role is in detailing the subduction of the oceanic lithosphere; what goes in and how that changes with depth. What happens to the sedimentary layer (Layer 1) that is only a few hundred meters thick? Does Layer 2 (basalt but

porous) experience an increase in seismic velocity with depth? These considerations may then lead to answering questions such as the following: Exactly where and how do the earthquakes occur over the trench area? What are the parameters that control the dynamic rupturing of large interplate earthquakes? Such pieces of information are not only unattainable from land observations but are also challenges to marine seismology.

On the other hand, the structure of the overriding plate is also important to the understanding of the consequences of plate interaction. Oceanic island arcs are believed to have formed from oceanic crust. Would this crust eventually disappear into mantle as normal oceanic crusts would? Once the subduction process starts, it has been postulated that two major environments exist: accretion and erosion (von Huene and Scholl, 1991). How do these processes contribute to the arc growth? These questions are again best answered by marine seismology.

In the western Pacific, there are many marginal seas. Are they different from normal ocean, as we often do not observe obvious magnetic lineation patterns or oceanic ridges? Such regionalized structures can only be studied by local-scale experiments (<100 km horizontal scale for crustal thickness structure). Although the scale is local, its significance can be global.

Figure 1 shows the Pacific Rim and various convergent margins where marine seismological investigations have been conducted.

3.1.1 Japan Trench

The Japan Trench area is one of the best areas to show the present status of the marine seismological understanding of an active *seismogenic zone* (Fig. 1b). Here the subduction of the Pacific plate takes place at a rate of about $8\text{--}9\text{ cm y}^{-1}$ with little obliquity. Beneath the east coast of northeast Japan, the top of the Wadati–Benioff zone is reliably determined by a land network at $\sim 50\text{ km}$ depth dipping at $\sim 25^\circ$. Historically, great ($M > 8$) thrust faulting earthquakes between 38° and 40° N seem to occur irregularly. However, $M7$ -class thrust faulting events are frequent (six events since 1968 to 1994 in the same zone). Large thrust type events are known to occur to about 100 km inward from the trench axis, where the intraplate double seismic zone takes over with overlapping with the thrust zone.

Marine seismological studies in the Japan Trench area have been conducted for many years since the 1960s. Many models have been constructed from two-ship and sono-buoy experiments (Ludwig *et al.*, 1966), from MCS experiments (Nasu *et al.*, 1980), and from OBS experiments (Suyehiro and Nishizawa, 1994). These controlled source experiments produced crustal models down to about 20 km from refraction profiles and down to 12 km from reflection profiles. From these studies, it became evident that the accretionary prism is little developed, requiring most of the sediments to be

subducted. Interpretation of OBS controlled-source data suggested that subduction of oceanic crust occurs at a dip angle of less than 5° to about 70 km landward of the trench axis (Suyehiro and Nishizawa, 1994).

Figure 2 compiles more recent results and therefore has more detail to larger depths (Hino *et al.*, 2000; Tsuru *et al.*, 2000). The observational features are: (1) the oceanic plate subducts at a shallow dip angle but abruptly increases its dip at about 20 km depth (bending front in Fig. 2); (2) a wide gap exists between the updip end of the seismogenic zone and the trench axis; (3) the deeper end of the seismogenic zone extends into the zone with contact to upper mantle of the continent side.

In 1994, the Sanriku-Haruka-Oki earthquake ($M_w 7.7$) occurred, after which many OBSs were deployed to observe aftershocks (Hino *et al.*, 2000). Aftershock mechanisms show inconsistent patterns, with interplate thrusts suggesting that many events occur outside the plate boundary. Also, this observation revealed that the aftershock activity was very low where the main shock released most of its seismic moment (bending front in Fig. 2). From an independent seismic structure experiment carried out in 1996 (Takahashi *et al.*, 2000), this zone seems to be where the contact with the continent side wedge mantle begins.

These inferences from marine seismology have important bearings on understanding the seismogenic zone in terms of what controls the shallow and deep ends as well as moment release distribution or asperities.

3.1.2 Nankai Trough

The Philippine Sea plate subduction beneath the Tokai crust has caused $M8$ -class interplate earthquakes to recur every $\sim 120\text{ y}$ with about 4 m slip ($\sim 3\text{ cm y}^{-1}$) (Fig. 1b). The last sequence of events were 1944 Tonankai and 1946 Nankaido earthquakes. The eastern limit of the rupture zone of the 1944 Tonankai Earthquake ($M 8$) is somewhat ambiguous, but many studies indicate about $137^\circ\text{--}137.5^\circ\text{ E}$, which leaves a possible rupture zone extending into the Suruga Bay along the Nankai Trough, which experienced large interplate earthquakes up until 1854. The seismic efficiency is nearly 100%, in contrast to the much lower Japan Trench area. There seems to be structural control over the rupture areas along the trough axis because all the estimated ruptures seem to start and end at certain areas. We will see in this section what structural control can be obtained from marine seismological results. Conclusive evidence is yet to come, but we are certainly progressing in resolving details that may be related to earthquake generation.

The most conspicuous bathymetric anomaly is the Zenisu Ridge, which is about to subduct beneath the Tokai area. It has been suggested that a so-called proto-Zenisu Ridge is already subducted preceding this ridge (Le Pichon *et al.*, 1996). If this is so, questions arise about what role such bathymetric

FIGURE 1 Marine seismological investigations are being made at many tectonically different locations where active plate tectonic processes are taking place. (a) Active margins of the circum-Pacific rim. (b) Northwestern Pacific rim. In this sector, the Pacific plate is old (>100 Ma) and subducting at a relatively fast rate (about 10 cm y^{-1}) in contrast to the young and slow Philippine Sea plate. (c) Northeastern Pacific rim. Small and young plates are subducting beneath N. America. (d) Eastern Pacific rim. (e) Southeastern Pacific rim. Seismological models at locations indicated by rectangles or thick lines are shown in the following figures.

anomalies play in the subduction tectonics and earthquake cycle.

3.1.2.1 Eastern Nankai District

OBS seismic surveys in the Nankai Trough began in 1992 (Nakanishi *et al.*, 1998). Figure 3 represents a cross section off

Tokai district from 25 OBSs where the Zenisu Ridge is approaching the trough (Nakanishi *et al.*, 1998). The seismic velocity structures on both flanks suggest the Ridge to be oceanic crust. The igneous crust section is about 8 km thick. The subduction of the Philippine Sea plate is imaged to about 34° N , where the top of the subducting igneous crust reaches

FIGURE 2 Seismological models across the northern Japan Trench (see Fig. 1b). (a) MCS model. Development and destruction of horst and graben structure at the top of Pacific Ocean crust before and after subduction can be observed. (From Tsuru *et al.*, 2000.) (b) Seismic velocities from OBS surveys are shown together with MCS interpretations. (From Tsuru *et al.*, 2000.) (c) Large interplate earthquake (M_w 7.7) in 1994 started from the position of the star and ruptured westward along plate boundary (thick curve) as indicated by arrow. Solid dots are aftershocks determined by a temporary OBS network. Seismicity by land network (gray dots) is biased beneath the marine area. (From Hino *et al.*, 2000.) (a) & (b) copyright by the American Geophysical Union.

FIGURE 3 Crustal structure across the eastern Nankai Trough where a bathymetric high (Zenusu Ridge) is approaching the trough (see Fig. 1b). (From Nakanishi *et al.*, 1998. Copyright by the American Geophysical Union)

about 12 km depth. The dip angle is only about 4° . Strong seismic coupling occurs below this depth. A dip angle of about 10° can be inferred from seismicity north of 34° N.

Beneath the south flank of the Zenisu Ridge, the Moho seems to become discontinuously shallower landward with an offset of 5 km in depth. This discontinuity coincides with the deeper extension of a major fault zone identified in reflection seismic record near the sea floor (Le Pichon *et al.*, 1996). Such a major fault suggests that the plate motion is accommodated in a much wider area than previously thought. Again, this sort of feature can only be identified by marine seismological techniques.

3.1.2.2 Western Nankai District

In contrast to the eastern part where the bathymetry is more complex, the western part is well known for its textbook-like subduction geometry as defined by MCS seismic records (e.g., Moore *et al.*, 1990). Recently a number of MCS/OBS transects were made in this well-defined accretionary prism area (Mochizuki *et al.*, 1998; Park *et al.*, 1999; Kodaira *et al.*, 2000a,b). Here, the plate dip angle is about 7° (see Color Plate 9(a)). Low seismic velocity prism material exists at least to 10 km depth.

Color Plate 9(a) shows two OBS structure models with seismicity from the land network. The 1946 Nankaido Earthquake fault models ("Earthquake dislocation area" in the plate) extend well into where the plate is in contact with the low seismic velocity accretionary prism. Another interesting feature is the imaging of a subducting seamount by MCS/OBS profiling (Kodaira *et al.*, 2000b). It is estimated to be 17 km in diameter, and seems to have acted as barrier to decelerate the seismic rupture of the 1946 event.

Large earthquakes in the Nankai Trough historically occurred in pairs with little or no time interval between the two events. Mochizuki *et al.* (1998) found structural heterogeneities both above and below the subducting plate boundary near the main shock epicenter of the 1946 event. This zone can be considered as being at the border of the two main rupture areas of Nankai Trough large earthquakes. Whether this feature is the asperity directly causing the pairing characteristics of the large events is not yet clear. However, this offers a structural constraint for any physical modeling of earthquake ruptures.

3.1.3 Other Pacific Rim Convergent Margins

We have seen two contrasting convergent margins above. The northeast Japan Trench is where fast and old plate is subducting, whereas the Nankai Trough is where slow and relatively young plate is subducting. In the following we will overview several of the other convergent margins with different subduction characteristics where modern marine seismological surveys have taken place. From these results, we are clearly gaining valuable information that can be acquired only by marine seismological methods. At this stage the variability among different margin settings or within each setting is still difficult to explain.

3.1.3.1 Cascadia

Cascadia subduction zone is where young (4–8 Ma) Juan de Fuca plate subducts at a slow convergence rate (ENE-ward at 4 cm y^{-1}) with high regional sedimentation rate beneath the North American continent (Fig. 1c). Large earthquakes are

rare, but the potential for significant activity seems to exist. Onshore–offshore seismic experiment revealed the subducted oceanic crust subducting at a small angle into well beneath the continental margin. Forearc crustal structure changes significantly along strike (Trehu *et al.*, 1994; Flueh *et al.*, 1998a) (Fig. 4a–c).

Flueh *et al.* (1998a) reported that the dip angle of the subducting plate is only a few degrees at about 47° N. The accretionary wedge is well developed and an increase of seismic velocity to $>4 \text{ km sec}^{-1}$ seems to be due to dehydration, compaction, and diagenesis. Velocities $>5 \text{ km sec}^{-1}$ may indicate igneous rocks that may sustain strain energy for seismic release.

Trehu *et al.* (1994) compiled an E–W cross section from previous results to show oceanic crust persisting beneath the coast with a larger dip angle than above (Fig. 4c). The Siletz terrane is exposed basement rock of the Cascadia forearc, which consists of accreted oceanic crust and seamounts about 50 Ma. Seismic velocities are much higher than observed by Flueh *et al.* (1998a). The terrane is bordered by lower seismic velocity subduction complex at about 100 km distance (75 km from deformation front). North American mantle starts from more than 40 km depth.

3.1.3.2 Nicaragua and Costa Rica Margins

The Cocos oceanic plate created at the East Pacific Rise is subducting at the Middle American Trench (Fig. 1d). The plate subduction rate is currently about 9 cm y^{-1} nearly perpendicular to the trench axis. The plate is relatively young at about 25–30 Ma.

The convergent margin off Guatemala, Nicaragua, and Costa Rica has been investigated by several MCS and OBS studies including a 3D seismic survey (Shipley *et al.*, 1992). Two hypotheses regarding the making of the margin involve whether the margin is composed of Neogene accretion materials or older (Mesozoic) ophiolitic rocks. Such a distinction is not simple from seismic data alone. Drilled core samples can indicate the origin from a particular spot and the seismic data can be used to extrapolate the ground evidence.

A 335 km long seismic profiling was made by shooting large airguns to Ocean Bottom Hydrophones (OBHs) and temporary land stations off Nicaragua (Walther *et al.*, 2000) (Fig. 4d). The OBHs were spaced at 10–25 km distance. The oceanic crust is 5.5 km thick. Seismic phases interpreted to be from the subducting Moho could be followed to a depth of 26 km, suggesting a clear seismic velocity change across the interface. From land station data, the plate dip angle is inferred to increase strongly at about 25 km depth beneath the continental shelf. Comparison with local seismicity shallower than 25 km depth indicates that many of the events occur above the subducting plate and do not show any clear correlation. However, this may be due to poor location of hypocenters. There is a seismicity gap between 25 and 40 km depth. Below 40 km depth, the earthquakes are located on or

mostly below the plate boundary. The gap seems to start as the mantle wedge comes into contact with the subducting plate. On the upper plate, a basement wedge that is 15 km thick beneath the continental shelf and thins to the trench changing seismic velocities from 5.2 to 3.5 km sec^{-1} is interpreted to be of ophiolitic rocks, that is, similar to drilled ophiolites.

Christeson *et al.* (1999) obtained a cross section at the Costa Rica margin transecting the Nicoya Peninsula (Fig. 1d, 4e). The plate dip angle increases less rapidly compared to off Nicaragua (Walther *et al.*, 2000). In comparison with other margins the seismic velocity in the margin wedge is higher, but is lower than in the adjacent Nicoya complex (Fig. 4e). Their interpretation is that the mantle wedge is of the same material as the Nicoya complex but has slow seismic velocity because of fracturing, alteration, or accretion processes. Interplate seismicity seems to start at about 14 km depth.

3.1.3.3 Chile Margin

Large airguns (3×32 liters) were shot in two profiles each of 200 km length at about 100 m spacing to OBHs and land stations to study the subduction structure in the Chile Trench region (Flueh *et al.*, 1998b) (Fig. 1e). Here the tectonic environment changes along the trench axis at about 33° S. To the north, the trench axis is sediment-starved and the deeper slab flattens with no Quaternary volcanism up to 28° S. The southern region is more characteristic of a normal margin with active volcanism and steep subduction plate dip angle. From these refraction profiles and with MCS profiles they could obtain laterally varying structure models to define the seaward extent of continental crust and the volume of recent accretionary prisms. The two profiles about 70 km apart in the same subduction regime showed marked differences without clear correlation to surface geology (Figs. 4f,g).

3.2 Izu-Ogasawara (Bonin) Arc

Oceanic island arcs, such as the Izu-Ogasawara-Mariana, Tonga-Kermadec, or Kurile-Aleutian arcs, are believed to develop from normal oceanic crust at plate subduction boundaries. The scale of an oceanic arc is typically a few hundred kilometers across, with only a small portion rising above sea level. Practically, only marine seismology can provide knowledge of its seismic structure. Eventually, these arcs may accrete to continents and become a component of the continental crust. Thus the crustal structure, as it bears on the process of crustal accretion and its composition, has global significance. We choose the Izu-Ogasawara arc crust as an example of marine seismological investigation of an oceanic island arc. We will see how the seismological results have been used to address the above problems.

The Izu-Ogasawara arc system located off the southern coast of Japan, extending more than 1000 km from north to south and 300–450 km wide, is where active rifting and

FIGURE 4 Crustal structure models across the northeastern Pacific rim (see Fig. 1c, d, and e). (a) Cascadia forearc at about 47.5° N. (b) Cascadia forearc at about 46.7° N. (From Flueh *et al.*, 1998a.) (c) Cascadia forearc at about 45° N. (From Trehu *et al.*, 1994.) Structure above the dashed line is modeled by onshore–offshore experiments. Open triangles are seismometers and filled triangles are shot points on land. RZ is reflective zone. (d) Nicaragua margin model. (From Walther *et al.*, 2000.) Here, the Cocos plate is subducting northwestward at about 9 cm y^{-1} . (e) Costa Rica margin model. (From Christeson *et al.*, 1999.) (f, g) Chile margin models at about 32.75° S and 33.5° S, respectively. (From Flueh *et al.*, 1998b.) subduction are occurring (Fig. 5). The arc formation was probably initiated about 48 Ma. Rifting during the Oligocene formed the forearc and back-arc basins, which resulted in the spreading of the Shikoku Basin (to 15 Ma) and the separation of Kyushu-Palau Ridge. The forearc contains an along-arc chain of serpentinite seamounts inferred to result from mantle diapirs.

In 1992, an extensive seismic survey was conducted across the northern Izu-Ogasawara (Bonin) Island Arc system at 32° 15' N between 138° and 143° E (Suyehiro *et al.*, 1996; Takahashi *et al.*, 1998) (Fig. 5). The marine seismological survey used controlled sources and local earthquakes to model the crust, the upper mantle, and the subducting slab. Seismic reflection profiles using an airgun array (17–60 liters) received by a 24-channel hydrophone consisted of the main transect and two-ship expanding spread profiles (ESP) along strike of the arc. Along-strike profiles were selected to sample

the forearc, rift zone, and backarc. A total of 46 OBSs were laid out 15–20 km apart to receive airgun and dynamite shots along these profiles to sample deep structure using wide-angle reflections and refractions. Two OBS seismic arrays were effectively configured to determine local shallow and deep seismicity across the arc, particularly beneath the forearc and rift zone.

From these data, many interesting features were discovered (Suyehiro *et al.*, 1996). The crust has quite different characteristics from an average ocean crust (e.g., White *et al.*, 1992). We will describe and discuss here two key features: (i) the middle crust confined beneath the arc has a velocity of $\sim 6 \text{ km sec}^{-1}$ extending as far east as the volcanic front and is thickest ($\sim 20 \text{ km}$) beneath the presently active rift zone; (ii) the Moho becomes obscure east of the VF, and extremely low velocity is observed beneath the forearc serpentinite diapir [see Color Plate 9(b)].

FIGURE 5 An extensive marine seismic survey layout in 1992 is shown. E-W profile transects from the Pacific side to Shikoku Basin side. Dots are OBS positions. Profiles marked ESP are two-ship wide-angle seismic profiles also recorded by OBS. Inset shows the studied Izu-Ogasawara arc.

Once a definitive structure model is established, one can compare with results from other experiments and look for similarities and dissimilarities considering the experimental design that mainly defines the uniqueness and variance of the model.

A $\sim 6 \text{ km sec}^{-1}$ middle crust has been found at least north of 31° N all the way to the Izu peninsula from previous results. It is not so clearly observed south of 30° N to the Mariana arc (Ludwig *et al.*, 1973; LaTraille and Hussong, 1980). Considering the technology available when these experiments were carried out, their results should not be regarded as negative evidence. More experiments with higher resolution are required to detail the structure.

The candidate rock to be the main component of this layer was related to granitoid plutons, more specifically tonalite, from exposed rocks at Izu peninsula and dredged tonalite samples from Izu-Ogasawara forearc. We can then estimate that granitoids may be produced in an oceanic island arc setting on the order of $500 \text{ km}^3 \text{ km}^{-1}$ along arc strike in volume and $\sim 10\text{--}25 \text{ km}^3 \text{ km}^{-1} \text{ My}^{-1}$ in growth rate depending on the formation time length of 20–47 My (Suyehiro *et al.*, 1996).

A lower crust with anomalously high P velocity ($> 7 \text{ km sec}^{-1}$) seems to coexist with the 6 km sec^{-1} layer. This characteristic seismic velocity resembles high-velocity lower crustal layers found at passive margins in the north Atlantic (e.g., Mjelde *et al.*, 1993).

It is generally considered that the plate interaction in the Izu-Ogasawara arc is weak, as evidenced by the lack of major earthquakes or accretionary prisms. A low seismic velocity zone in the overriding crust hosting serpentinite seamounts suggests water release from the subducting crust. As the plate subducts further, the mantle wedge has seismic velocity less than 7.5 km sec^{-1} , which may be explained as serpentinization of the mantle peridotite due to further release of water from the subducting plate. At this depth west of 141.5° E , earthquake mechanisms are no longer of down-dip thrust type. This suggests that the seismogenic zone turns to stable sliding at about only 20 km depth, which may be due to the weakened overriding mantle.

The OBS microseismicity revealed that the Pacific Plate subducts at a dip angle of about 10° to as far west as past the forearc basin, where the dip angle increases significantly. Independent seismic evidence for shallow dipping plate comes from dynamite shot waves reflected off the top of the plate boundary. Although other subduction zones show an aseismic zone immediately landward of the trench axis, such a feature is not observed here.

This kind of experiment employing multiple seismic methods and more than one ship is not easy to undertake, but has proven to be powerful in imaging a large area and giving a comprehensive view of the region, in this case an oceanic island arc. However, there remain ambiguities as to how the crustal materials are linked with various igneous activities that

have operated in the region. A more detailed image is needed, such as by incorporating seismic scattering, anisotropy, or the attenuation characteristics of the crust.

3.3 Backarc Basins

The backarc basins or marginal seas are mostly developed in the western Pacific area. The Philippine Sea comprises a number of such basins forming the largest entity in this category. Others include the Japan Sea, South China Sea, Okhotsk Sea, Bering Sea, etc. They seem to have formed as a consequence of plate subduction, although there is no direct evidence to support this. One of the first questions to ask is what sort of crust is formed. Is there any significant difference from the crusts of major oceans? Do they evolve differently from normal oceans?

The geological history inferred from magnetic anomalies and drilling indicate rather complex evolution; that is, there does not seem to be a simple ridge system to create these basins. This is why using surface waves observed at long distances is not adequate to address the problems associated with the basin formation and development, although teleseismic observations are useful in capturing the average structure at lithosphere scale. We will see how marine seismological observations have brought the structural complexities to light, taking as an example the case of the Japan Sea.

3.3.1 Japan Sea—Mode of Opening, Present Stress Field

The Japan Sea was created as a consequence of the Japan arc separating from the Asian continent during a period about 20–15 Ma. However, observed magnetic anomalies do not show any clear evidence of sea-floor spreading.

Since 1985, a number of modern seismic surveys have been carried out in various parts of the Sea. The first of the series, in 1985, proved the importance of simultaneous observation of reflection and refraction waves. Beneath the flat bathymetry, the basement structure was rugged. From this and the following surveys, the complexities of the Japan Sea crusts were largely revealed.

Much of the basin areas is found to possess crust more than 10 km thick beneath sediments, except in northeastern Japan Basin where the crust is indistinguishable from that of a normal ocean. P wave velocities of about $6.6\text{--}7.1 \text{ km sec}^{-1}$ characterize the lower 70–80% ($\sim 8 \text{ km}$ thickness) of the Japan Sea crust. This suggests that a layer characteristic of granitic component of continental origin is thin in the basin areas, if there is any.

How the opening started in the Japan Sea is still uncertain. At passive margins, a number of locations are found to possess a high seismic velocity lower crust, interpreted to be due to magma intrusion during the rifting stage (e.g., White *et al.*, 1987). Its characteristic seismic velocity is $\sim 7.2 \text{ km sec}^{-1}$,

with a small gradient. A similar feature is also found in the lowermost part of the Japan Sea crust.

A detailed seismic survey was conducted in the northern Yamato Basin, where an ocean broadband downhole seismometer was installed together with a temporary array of nine OBSs. The upper crust was found to possess azimuthal anisotropy of about 4–7% in *P*-wave velocity, likely due to opening of cracks induced by the present state of stress, which is E–W compression (Hirata *et al.*, 1992). This shows another possibility for studying stress condition where earthquakes are rare.

4. Marine Seismic Instrumentation

In this section we overview the characteristics of marine seismometry, focusing on observing seismic signals beneath the sea water mass. The progress of marine seismology is rapid. We will emphasize the unique challenges marine seismologists are facing in order to obtain high-quality data from the oceans.

4.1 Basics

4.1.1 Ocean-Bottom Seismographs

An ocean-bottom seismograph (OBS) typically consists of the following components; the sensor (e.g., three-component plus hydrophone) with a leveling mechanism, controlling electronics to amplify/filter/digitize as necessary to feed to recorder, a real-time clock, and a power supply. These components are housed in pressure vessels to withstand the pressure of average ocean basin depths (5–6 km) to trench depths (4–10 km). A typical OBS is deployed from a vessel without tethers to sink to the bottom by its own weight. After its planned observation period, it can pop up to the sea surface by releasing the anchor weight on an acoustic command from the surface.

The areas of interest can range from ocean ridges with little sediment and rugged topography to trenches with escarpments. Sea-floor bathymetry must be known before deployment so that steep slopes can be avoided. OBS deployments have been made from vessels small fishing boats up to large vessels, and from helicopters.

4.1.2 Location and Clock Accuracy

The position of deployment can easily be determined within 100 m accuracy by the GPS system, which was not fully available until the early 1990s. The actual OBS location can be further improved by acoustic ranging (transponder communication or controlled-source recordings).

It is now quite easy to obtain 1 μ s GPS accuracy anywhere on the globe. The crystal oscillator (typically 10^{-7} – 10^{-8} accuracy) inside the OBS package is calibrated against this signal before and after deployments. For long-term

TABLE 1 Sensor Type and Power Requirement

Sensor Type	Power Requirement	Remarks
Moving-coil velocity sensor	Nil	Frequency response inadequate for teleseismic studies
Feedback broadband sensor CMG-1 (GSL)	12 V at 32 mA (0.38 W)	FDSN standard
PMD-2023 (PMD)	12 V at 22 mA (0.26 W)	Broadband, robust
KS-54000 (Teledyne)	24 V at 0.1 A (2.4 W)	FDSN standard

deployments, an acoustic link can be designed to calibrate the clock during observation. Direct water wave signals from many controlled shots can also be used for calibration.

4.1.3 Frequency and Dynamic Range

Electromagnetic velocity sensors with 1–4.5 Hz natural frequencies are often used because of their ruggedness, absence of power requirement, and small size. One 17-inch (43 cm) diameter glass sphere (two hemispheres to house instruments) can hold all the components if 4.5 Hz is selected. Adopting a lower-frequency type makes the system larger but allows better registration of low-frequency signals from teleseismic events. Broadband sensors are now beginning to be adapted for marine seismology (Table 1).

The dynamic range in effect is determined by the recording system. Analog recording technology required different gain channels to cover more than 40 dB. Digital technology now allows >16-bit (>96 dB) range and large-capacity storage (>a few Gbytes) to be adopted by an inexpensive OBS.

4.1.4 Power Supply and Data Storage

All the OBSs use batteries of various types such as alkaline or lithium dry cells. A low-power OBS (1 W) can run continuously for more than a month on C-size dry cells packed in a 17-inch pressure housing. For investigations of structures using active sources, a few weeks' observational window would suffice, since shooting ships can cover about 200 km per day. Natural earthquake observation usually needs a certain length of observation period depending on the target events according to the Gutenberg–Richter relation. Newer OBSs with larger pressure vessels are able to store digital data and maintain clock accuracy for several months to a year.

4.2 OBSs for Mobile Arrays

4.2.1 Seismic Profiling with OBS Arrays

By the 1980s, ocean-bottom seismographs were proven to be more effective and reliable for marine deep seismic sounding than the use of surface measurements using hydrophones.

Typically, an OBS record section will show oceanic Moho wide-angle reflection arrivals with a single airgun source with about 10 liter capacity shot at about 100 kg cm^{-2} . With 1 ton of dynamite, mantle waves can be observed over 1000 km distance.

Tens of OBSs can be deployed by the leap-frog method achieving, say, 300 km of profile length with 10–20 km spacings (e.g., Iwasaki *et al.*, 1990). It is not rare that up to 100 instruments are deployed in one operation. This allows two-dimensional OBS surveys with 1–2 km spacing with profiles of a few hundred kilometers.

We cannot overlook the importance of the reflection seismology method, which acquires acoustic data by hydrophone streamers (multiple and a few kilometers long) towed behind a shooting vessel. It is often important to combine both the OBS and seismic reflection datasets to resolve the structure in detail to large depths.

4.2.2 Natural Earthquake Studies Using OBS Arrays

OBS arrays are the best tool for analyzing submerged plate boundaries. OBS arrays can be deployed immediately after a large event to define the main fault plane, as well as its unevenness and complexities. Continuous and real-time seismic monitoring systems are being realized and are increasing, particularly near the coast of Japan.

Operating OBS regional arrays for more than several months to record distant natural earthquakes can reveal important features of the upper mantle. Features such as the deep roots of bathymetric highs (ridges, large igneous provinces, swells, or hot-spots) or how the subducted slabs affect the mantle are now becoming feasible targets.

4.3 Progress toward Permanent Broadband Observatories

The need for long-term ocean-bottom seismic observatories has been recognized since the early days of marine seismology. It is a formidable task, however, to sustain such stations, that is, to supply power and be able to store and retrieve the data. For an FDSN standard station, a broadband sensor is required. Then, together with a three-channel 24-bit digitizer (1.3 W), a real-time clock (5 V at 12 mA), and a data recorder (20 samples/sec for three channels of 24-bit data amount to about 6 Gbytes/year), about 4 W power supply would be a minimum requirement. Also, previous knowledge of noise characteristics is important for a long-term commitment (Webb, 1998).

It is generally conceived that installation in a borehole in intact rocks is superior to sea-floor deployment. Permanent stations of FDSN standard may require borehole installations at about 20 locations around the globe where no land/island exists within 2000 km distance. The efforts in this direction are briefly summarized in Table 2. At Hole 794D, the noise level was generally lower than at island or sea-floor stations, and was as low as about $10^4 (\text{nm sec}^{-1})^2 \text{ Hz}^{-1}$ at about 0.2 Hz, where normally a noise peak is found. Signals from local events and airguns exhibit less reverberation as compared with OBS records. Surface wave dispersion from an event ($M_b = 5.4$) at 39° distance was clearly observed. The French experiment brought about the first comparative results on broadband seismic signal spectra of borehole (OFP) and buried (OFM) sensors. While the noise levels were generally low, less noise was found below 0.1 Hz with OFM than with OFP. The temperature change in the borehole was larger than on the sea floor. A more comprehensive test was conducted in

TABLE 2 Specifications of Borehole Sensors

	Broadband Sensor	Frequency	Dynamic Range	Resolution	Power	Power Supply	Installation	Operation	Reference
Hole 794D	Guralp Slimline CMG-3	DC-30 Hz	112 dB	10^{-7} m s^{-2}	Approx. 20 W (incl. cable loss)	24 V 38 AH $\times$ 20	Japan Sea; drill ship	1989 Sep.	Suyehiro <i>et al.</i> (1992, 1995)
Hole 396B	Guralp CMG-3			10^{-9} m s^{-2}			Mid-Atlantic Ridge; manned submersible	1992 May	Montagner <i>et al.</i> (1994)
Hole 843B	Teledyne Geotech KS54000	3 m–4 Hz	24-bit	$2400 \text{ V m}^{-1} \text{ s}^{-1}$	sensor-2.4 W	NA	Wireline reentry	1998 Feb.–Jun.	Collins <i>et al.</i> (2001)
Holes 1150/1151	Guralp CMG-1	3 m–50 Hz	24-bit	$1500 \text{ V m}^{-1} \text{ s}^{-1}$	$< 5 \text{ W}$	18 W sea water battery	Drillship	1999 Jul.–Aug.	Araki (2000)
Hole 1172	Guralp CMG-1	3 m–50 Hz	24-bit	$1500 \text{ V m}^{-1} \text{ s}^{-1}$	$< 5 \text{ W}$	15 W sea water battery	Drillship	2000 Aug.	

1998 off Oahu in Hole 834D. Three-month long broadband records were obtained together with a station in Oahu, on the sea floor and buried in sediment. A significant improvement in noise level was confirmed for the buried and borehole systems compared to the sea-floor system.

In the coming years, it is expected that the number of observatories will increase to fill the global gaps as well as for monitoring active geological processes together with other sensors. The installation of sensor and recording systems can be carried out using one of several existing general- and special-purpose manned submersibles or ROV systems. Modularity, common components, and standardized formats to reduce costs and provide ease of maintenance are desirable.

5. Data Analyses

Seismological data analyses are basically the same as those applied to data obtained on land. For example, when locating earthquakes, one must take into account OBS depths in a similar manner to when handling land station heights. We note in the following some characteristics pertinent to marine controlled-source seismic data.

5.1 Reflection Seismic Surveys

The basic idea of reflection seismic surveys is to make a sectional picture of sub-sea-floor structure by plotting observed seismic waves reflected from interfaces, where seismic impedance (the product of density and seismic velocity) changes. In marine environment, seismic waves generated by artificial seismic sources are received by single or multiple arrays of hydrophone receivers. An airgun array is used to shape the signal waveform into an impulse-like signal. Both source and receiver arrays are towed behind a vessel (Fig. 6a). In general, the wider the aperture of the source–receiver configuration, the deeper the structural target can be. The shorter the channel separation, the higher is the spatial resolution. A basic flow of data analysis consists of the following:

- Data sorting, in which data are grouped by common spatial reflected points (common mid points; CMPs).
- Deconvolution, in which observed waveforms are processed to improve the temporal resolution.
- Seismic velocity analysis, in which seismic velocity structure is determined.
- Normal moveout (NMO) correction, in which traces are stretched according to the velocity structure so that CMP-gather traces having different angles of reflection are mapped onto the vertical axis through the CMP to represent zero-offset reflection (any returned signals are mapped to this single vertical trace as if acoustic impedance changes existed vertically below).

- Stacking, in which NMO-corrected traces are added in order to increase the signal-to-noise ratio (Fig. 6a).
- Migration, in which dipping reflectors and diffracted energy are mapped to their true locations. (This process is intended to move the reflection energy back to its original location (Fig. 6b).)

Detailed explanations of each process can be found in general texts (e.g., Yilmaz, 1987; Bancroft, 1998).

5.2 Refraction Seismic Surveys

In most cases, refraction surveys are carried out using ocean-bottom seismometers with OBSs are deployed on the sea floor along profiles to observe seismic waves generated on the sea surface. This is the main difference from land seismic observations. One must take care of the water depth layer in analyses of observed seismic waves. Formulas for land experiments are often written for a series of seismic signals from a single shot point to many receivers. In the marine case, the data are often assembled in a series of many shots to each OBS. Therefore, when amplitudes are considered, one cannot simply interchange source and receiver from codes for land experiments to correctly calculate amplitude variations. Also, the acoustic basement beneath soft sediments often acts as a good phase conversion interface, more so than the sea floor.

6. Concluding Remarks

In this chapter we have mainly seen the present status of marine seismology from observational examples in the Pacific. Clearly, there is still much room for improvement, particularly in the observational aspects. While most earth scientists will agree that marine seismological investigations should provide fundamental knowledge for understanding the Earth's dynamics, the technical challenge of achieving good-quality observations has been formidable. Starting from scratch, we have come a long way in the last half a century or so.

Controlled-source seismology has often been performed with many shots and a few receivers, which is the opposite of land experiments. However, nowadays, 100-OBS experiments are feasible and are being done together with deep-penetration seismic reflection experiments. Ships allow very flexible and optimal designs of seismic experiments. Steps are being taken to illuminate 3D structures, such as subducted seamounts, magma chambers, or pathways of fluids (e.g., Bangs *et al.*, 1999). High-resolution deep-penetration modeling of laterally heterogeneous structures at plate boundaries will continue to be exciting, with more and more focused targets.

Attempts to establish long-term seismic observatories have been less successful, but recent results are encouraging and with international cooperation it is expected that the global seismic network will finally truly cover the whole globe in
